The density of the somas of most retinal cell types is rarely so great as to crowd them together side-by-side. Where density is this great, the cells may approximate a hexagonal packing by virtue of this physical constraint of crowding circular profiles into a fixed space (Curcio, C. A. and Sloan, K. R., 1992). More commonly though, cell density is far lower than permitted by maximal packing. Under these circumstances, the distribution of a given type of cell still exhibits a degree of local order – the cells appear to be regularly arranged (Figure 2). The average intercellular spacing is typically large relative to the physical size of the cell bodies, yet this spacing is not imposed by any general physical constraint prohibiting somal positioning because cells of other type are positioned between these cells. Such regular arrays of nerve cells are commonly known as retinal mosaics because of the way they appear to tile the retinal surface uniformly, establishing territories of comparable size (Wässle, H. and Riemann, H. J., 1978). As we shall see, the notion of tiling has come to

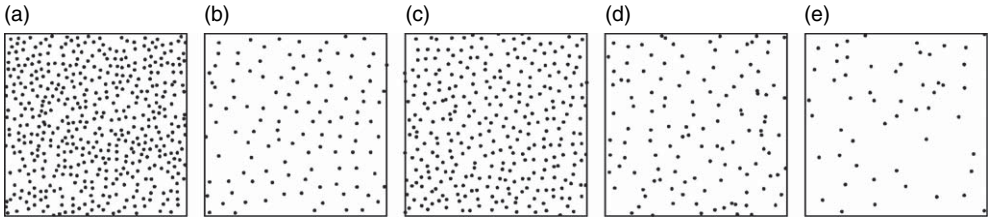

Figure 2 Local distribution of nerve cells for five different retinal cell types: (a) rod photoreceptors, (b) S cones, (c) B-type (axon-bearing) horizontal cells, (d) displaced cholinergic amacrine cells, and (e) dopaminergic amacrine cells. The images in (a) and (b) are from the ground squirrel retina, scaled identically, at local densities of approximately 12 000 cells mm^{-2} and 3000 cells mm^{-2} (Galli-Resta, L. *et al.*, 1999); those in (c–e) are from the mouse retina at varying magnifications, where average densities are 1600 cells mm^{-2}, 1400 cells mm^{-2}, and 36 cells mm^{-2} respectively (Raven, M. A. and Reese, B. E., 2002; Raven, M. A. *et al.*, 2003; Farajian, R. *et al.*, 2004). The mosaics of all five cell types differ from random distributions of cells. The average regularity indexes associated with these mosaics, derived from nearest neighbor analysis, are 6.0 (a), 5.5 (b), 4.9 (c), 3.3 (d), and 2.7 (e).

have a more specific meaning in association with the manner by which the dendritic fields associated with these cells distribute themselves relative to one another. For the moment, let us consider the means by which such arrays of retinal neurons can be objectively assessed for their orderliness.

1.22.2.3 Assessing the Local Order of Retinal Nerve Cells

1.22.2.3.1 Nearest neighbor analysis

The classic means of analyzing the regularity within such mosaics has been to measure the distance of each cell within the mosaic to its nearest neighboring cell (Wässle, H. and Riemann, H. J., 1978). While the absolute distance of such nearest neighbor measurements for a population of cells varies as a function of local density (Figure 3), when the variance in the population of nearest neighbor distances is taken into account by dividing the mean distance by the standard deviation, this ratio, commonly called the regularity index (Vaney, D. I. *et al.*, 1989) or conformity ratio (Cook, J. E., 1996), permits an appreciation of how the local order in a population is maintained across such variation in density.

Of course, such a ratio has no upper limit: as the variance in intercellular spacing approaches zero, say in association with a perfect square or hexagonal matrix, the ratio approaches infinity. In practice, a ratio of 5.0 or 6.0 is generally regarded as being regular (Figure 3), but little significance is generally attached to such differences. At the lower end of the scale, however, the ratio approaches the theoretical lower limit of 1.91 achieved by a population of infinitely small points that are randomly distributed within a field (Cook, J. E., 1996). Here, it is interesting to ask whether a population of cells is more regularly distributed than a random distribution, and most uses of the analysis have sought to determine only this. The distribution of nearest neighbor distances for the real population of cells is usually compared with that derived from a random distribution of points of identical density. That latter distribution approximates a Poisson distribution, while the distribution of nearest neighbor distances for many real mosaics approximates a Gaussian distribution (Figure 3). To the extent that a real mosaic more closely conforms to the latter, with a regularity index above 2.0, so the mosaic is said to be regular. Such a mosaic is sometimes qualified as 'highly' versus 'marginally' regular (e.g., Figure 2), depending on how different the mosaic is relative to random.

In some circumstances, retinal nerve cells may overlie one another where a nuclear layer is greater than a single cell thick. More often than not, cells of a given type are confined to a single stratum, even within a multicellular nuclear layer, so their physical size constrains them from getting closer to one another than the distance of an average soma size. For this reason, a more conservative comparison for addressing deviation from randomness would be with a random distribution of elements matched in density to the real population and assigned physical sizes drawn from the soma size distribution for that population (Figure 4, top). Such constrained random simulations maintain their generally Poisson characteristics (Raven, M. A. *et al.*, 2003), though they are truncated at the shortest distances, and consequently yield regularity indexes that differ substantially (particularly for higher density mosaics) from the theoretical value for a random distribution of points. For example, random simulations for the population

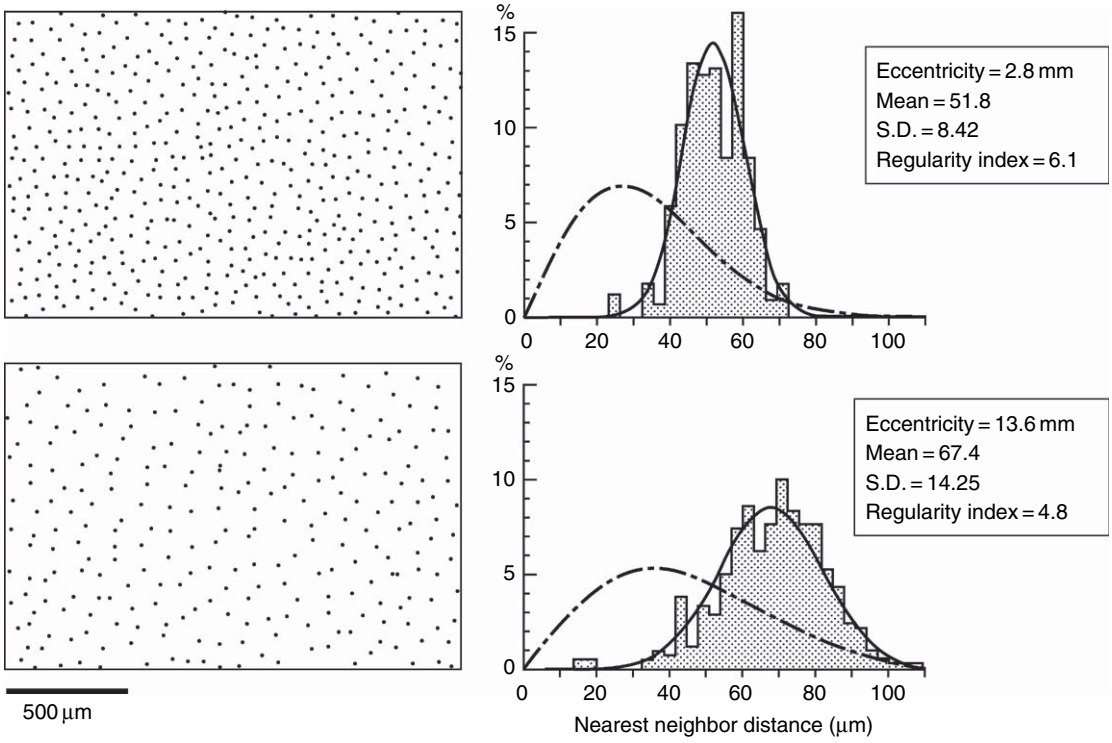

Figure 3 Mosaic of A-type (axonless) horizontal cells from the cat retina at two different eccentricities from the area centralis. As cell density declines with eccentricity, so the average intercellular spacing increases. The histograms show the nearest neighbor distances for these same fields; solid lines show the gaussian curve for a distribution with the same mean and standard deviation, while the broken lines show the Poisson distribution at identical density; this is the theoretical curve expected for a random distribution of points. Adapted from Wässle, H. and Riemann, H. J. 1978 The mosaic of nerve cells in the mammalian retina. Proc. R. Soc. Lond. B. 200, 441–461, with permission from The Royal Society, London.

of horizontal cells in the mouse retina generate regularity indexes derived from nearest neighbor analysis greater than 3.0 (Raven, M. A. and Reese, B. E., 2002), a value generally regarded as evidence of regularity. Real distributions of horizontal cells are still readily distinguishable from such random simulations, yielding regularity indexes around 5.0. Clearly, the physical constraint imposed by soma size will have an increasingly pronounced effect upon a random simulation as a function of its density. The regularity index then is less an objective yardstick for describing some feature of local order than it is a relative measure, and the magnitude of any difference from a random distribution will depend upon the assumptions defining the random simulation with which it is being compared.

One other criticism of the use of the nearest neighbor analysis is that it is dependent only upon relationships between each cell and its closest neighbor rather than factoring in relationships between all surrounding neighbors, and as such, will not discriminate between arrays that differ conspicuously in their spatial distribution. For example, a linear distribution of equally spaced points and a square matrix of cells with the same periodicity are identical in their nearest neighbor statistics, but only one distribution provides a uniform sampling across a two-dimensional surface. Within the retina, the ballroom dancers analogy provides an apt illustration of the point: nearest neighbor analysis will not discriminate between a pattern made up by pairs of dancers of low density versus pairs that fill the ballroom (Cook, J.E., 1996). Nearly random low-density distributions of cells occasionally yield high nearest neighbor regularity indexes for this reason (Raven, M. A. *et al.*, 2003). At higher densities, a regular array in which, for instance, every fifth cell is missing will not be discriminated from the intact array by nearest neighbor analysis. A few missing elements may reflect slight undersampling, and not perturb the nearest neighbor statistic significantly (Cook, J. E., 1996), but they may also be indicative of real biological

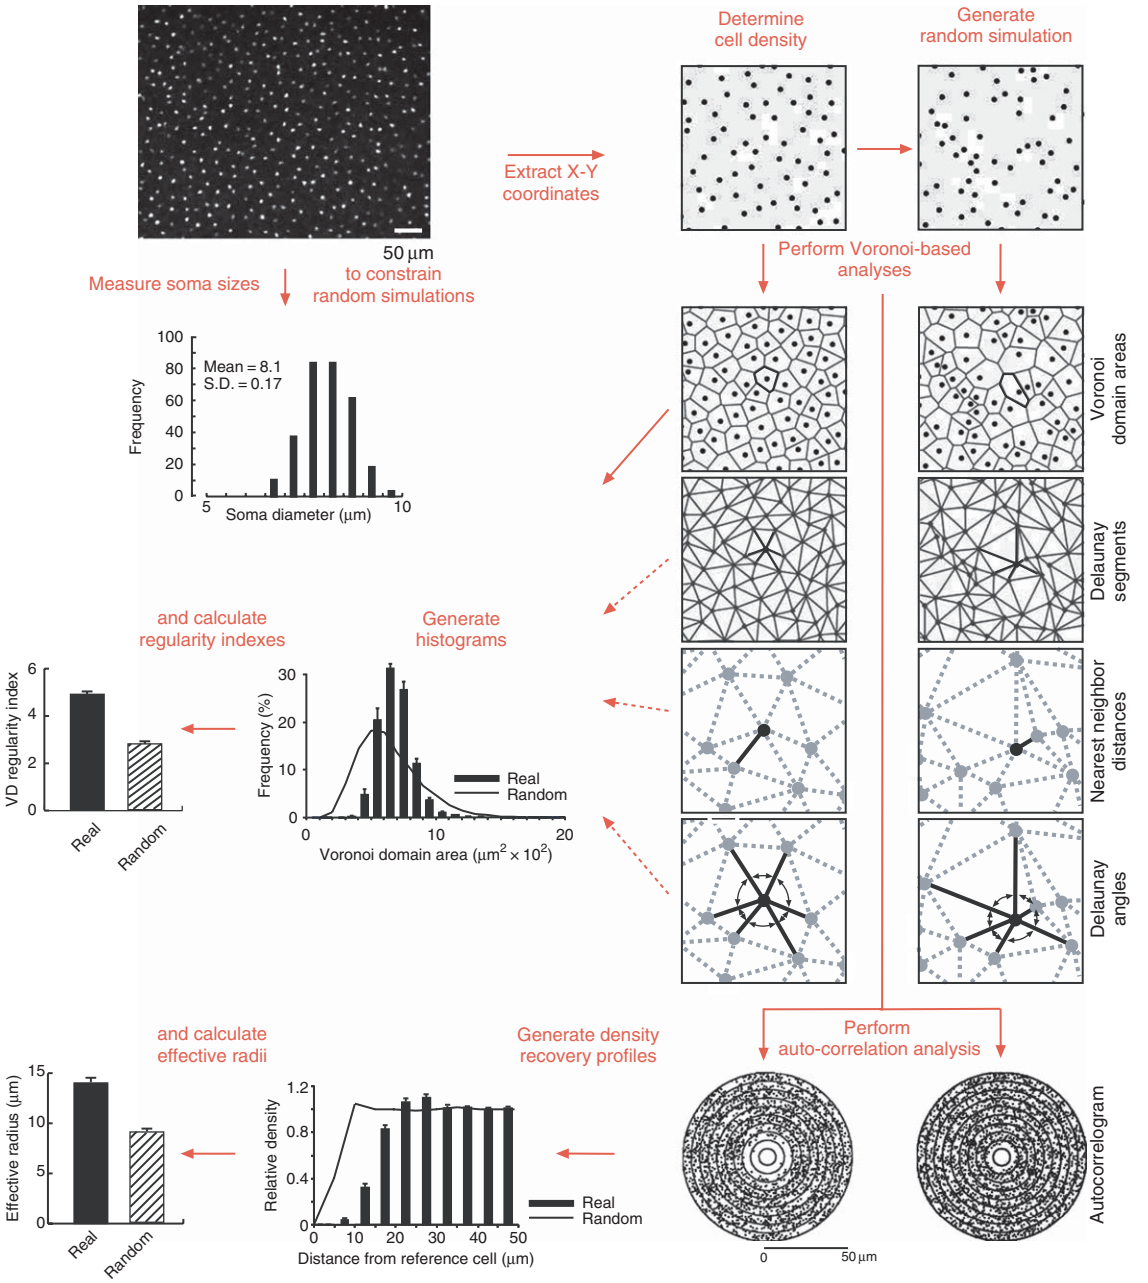

Figure 4 Assessing mosaic organization using Voronoi-based and autocorrelation analyses. Top: sample fields of cells (e.g., horizontal cells in the mouse retina) are analyzed for cell density and soma size, from which random simulations of cells matched in density and soma size are generated for comparison. Middle: from these real and random fields, Voronoi-based analyses are conducted and compared. Shown here are the Voronoi domain areas, the Delaunay segment lengths, the nearest neighbor distances (being the shortest Delaunay segment for each cell), and the Delaunay angles. These can be compared for the real and random simulations as frequency histograms or regularity indexes (only those for Voronoi domain areas are shown). Bottom: the autocorrelation analysis reveals the presence of an exclusion zone, the size of which can be estimated from the density recovery profile, termed the effective radius.

variation (Galli-Resta, L. *et al.*, 1999), and only a fuller analysis of the geometric relationships within the mosaic will allow a discrimination of such a difference.

1.22.2.3.2 Voronoi-based analyses

Other measures of mosaic order that take into consideration the relationship between each cell and all of its immediate neighbors have increasingly come

into favor (Shapiro, M. B. *et al.*, 1985; Ammermüller, J. *et al.*, 1993; Cellerino, A. *et al.*, 2000; Galli-Resta, L., 2000; Galli-Resta, L. and Novelli, E., 2000). Many of these are derived from Delaunay triangulation, connecting all of the cells to their immediate near neighbors (Figure 4, middle). Measuring the lengths of all Delaunay segments within a field, in both real samples and random simulations, is one such means to compare better their two-dimensional patterning, as is measuring the volumes of those triangles, or the angles defined by them. Another is to measure the Voronoi domain associated with each cell in the array, being the area within the plane of the array defining all points closer to each cell than to any other cell (and being identified by the intersections of all of the bisectors of the Delaunay segments). The reciprocal of the Voronoi domain area of a cell is therefore the local cellular density. The mosaic of Voronoi domains also has the attractive feature of approximating the tessellating nature of nonoverlapping dendritic fields (see further). All of these measures are related to one another but some prove more discriminating than others (Galli-Resta, L. *et al.*, 1999; Zhan, X. J. and Troy, J. B., 2000; Raven, M. A. *et al.*, 2003; Eglen, S. J. *et al.*, 2003b). Some researchers have used the coefficient of variation, being the ratio of the standard deviation of the Voronoi domain areas to the mean area, in an attempt to discriminate clustered, random, and regular arrays, either locally or across the retina (Curcio, C. A. and Sloan, K. R., 1992; Duyckaerts, C. and Godefroy, G., 2000; Palanza, L. *et al.*, 2005), this measure being the inverse of the Voronoi domain regularity index described in Figure 4. The general benefit of any of these analyses is that they encompass the geometric features of a two-dimensional array more thoroughly than does the nearest neighbor analysis.

1.22.2.3.3 Autocorrelation analysis and the density recovery profile

Still others have advocated the use of autocorrelation analysis and the density recovery profile derived from it, pioneered by Rodieck (Rodieck, R. W., 1991). The autocorrelogram of a field of cells is the plot of the position of all cells relative to every other cell, generated by placing the first cell in the array at the origin of the autocorrelogram and then plotting the position of all the other cells in the array relative to it, and then repeating this for each cell in the array. For a population that is distributed as a quasiregular lattice, that periodicity will reinforce itself and become more readily detectable as regions of high and low density at repeating intervals within the autocorrelogram. Most retinal mosaics do not contain such higher-order periodicity. Rather, the autocorrelogram usually reveals the presence of an exclusion zone at the origin (Figure 4, bottom), indicating that cells are less likely to be positioned near one another. Such exclusion zones have been taken as evidence for regularity in retinal mosaics (Cook, J. E., 1996; Rockhill, R. L. *et al.*, 2000) but it is not always the case that the presence of an exclusion zone, nor the size of it relative to soma size, reveals a regular mosaic (Galli-Resta, L. *et al.*, 1999; Raven, M. A. *et al.*, 2003), specifically, when packing intensity is low. (The packing intensity describes the extent to which the field is covered by nonoverlapping disks of a diameter associated with the average nearest neighbor distance within the field, being low for a field such as that in Figure 2(e)) (see Diggle, P. J., 2002).

Autocorrelation analysis, like the use of nearest neighbor and Voronoi analyses mentioned earlier, requires a consideration of the size of the cell body for cell types that are distributed in a single stratum, because the soma size itself defines an exclusion zone surrounding the position of each cell. The exclusion zones associated with real versus random arrays can be quantified and compared by constructing the density recovery profile derived from each autocorrelogram (Figure 4, bottom), being a histogram plotting the density of cells at increasing distances from the cell body, and from this, calculating the effective radius, being the radius of a cylinder with a volume equivalent to the empty region at the origin of the autocorrelogram (Rodieck, R. W., 1991). It should be obvious that the distribution of nearest neighbor distances for a field of cells overlaps with the initial slope of the density recovery profile. Consequently, the size of the effective radius is directly related to the mean nearest neighbor distance (Figure 5(a)) (Cook, J. E., 1996). Nearly all retinal mosaics that have been analyzed using this approach reveal the presence of such exclusion zones extending beyond the size of the cell body (Rockhill, R. L. *et al.*, 2000; Tyler, M. J. *et al.*, 2005). More often than not, the positioning of cells in such mosaics is independent of other mosaics in the retina, evidenced using cross-correlation analysis, including those that are either afferent to, or targets of the mosaic cells in question (but see Kouyama, N. and Marshak, D. W., 1997; Ahnelt, P. K. *et al.*, 2000). Together, those results have led to the conclusion that the rules governing cellular positioning within a

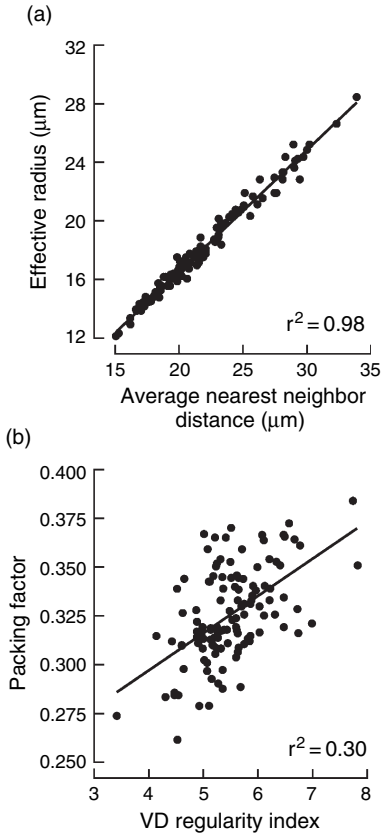

Figure 5 The scale-dependent effective radius is highly correlated with average nearest neighbor distance (a), the former measure being about 83% of the latter for the present dataset. The packing factor, like regularity index, is a scale-independent measure, but bears only a slight relationship to a field's regularity index derived from either nearest neighbor or Voronoi domain analysis (b). Data are from 121 fields of mouse horizontal cells drawn from four strains showing a twofold variation in horizontal cell density. From Raven, M. A., Stagg, S. B., and Reese, B. E. 2005a. Regularity and packing of the horizontal cell mosaic in different strains of mice. Vis. Neurosci. 22, 461–468.

mosaic involve interactions with only like-type neighbors (Reese, B. E. and Galli-Resta, L., 2002).

Because the detection of such an exclusion zone depends upon the size of the annuli used (the choice of which is influenced by the density of the cells in the field), an alternative is to plot a cumulative version of the density recovery profile (Ripley, B. D., 1976; Diggle, P. J., 2002), that is, the cumulative frequency histogram of intercellular distances between all cells within the array. This plot describes the fraction of intercellular distances that are above or below a given distance, and is compared with cumulative histograms for random simulations. The analysis is typically combined with Monte Carlo testing by generating 99 random simulations constrained by density and soma size to discern whether the real biological mosaic deviates from the envelop of the random simulations (Raven, M. A. *et al.*, 2003; Eglen, S. L. *et al.*, 2003b; Hofer, H. *et al.*, 2005). A reduction in the frequency of shorter intercellular distances (relative to random) is indicative of the presence of an exclusion zone, while an increase in the frequency of shorter intercellular distances is indicative of clustering of the cells. Such deviation from random can be determined by eye, or more objectively by a ranking test, in which the difference between the plot for each random simulation (and real distribution) and a Poisson distribution is calculated, and then ordered to allow the assignment of a p value to test for spatial randomness (Diggle, P. J.,1986). Such Monte Carlo analysis is particularly beneficial for analyzing small or single samples, not uncommon for rare specimens, but the inferences drawn from it are only as sound as that sample mosaic is truly representative of the population.

The tessellation-based analyses described above can discriminate between different spatial point patterns that have identical properties detected in the above correlation-based approaches, and so some have advocated the employment of both approaches in describing the distribution of retinal nerve cells (Shapiro, M. B. *et al.*, 1985; Raven, M. A. and Reese, B. E., 2002; Raven, M. A. *et al.*, 2003) as well as other means, for instance, quadrat analysis (Grieg-Smith, P., 1964), for addressing the longer-range spatial patterning present across a population (Tyler, M.J. *et al.*, 2005). The use of multiple approaches is particularly desired when seeking to model a retinal mosaic, as the model should replicate multiple features of the spatial distribution.

1.22.2.3.4 Packing factor analysis

For populations that do differ from random, the boundless regularity index as a descriptive statistic has its limitations in conveying a sense of the order within the mosaic. One alternative has been to describe how much the cells of a mosaic diverge from a regular lattice by examining the extent to which a lattice with known jitter can simulate the real mosaic (Shapiro, M. B. *et al.*, 1985; Curcio, C. A. and Sloan, K. R., 1992; Zhan, X. J. and Troy, J. B., 2000). A related descriptor has been to calculate the packing factor associated with the cells in a mosaic, it being the square of the ratio of the effective radius to the maximal radius permissible if a population of cells of identical density had been packed as a regular hexagonal matrix (Rodieck, R. W., 1991). Packing factor analysis provides an index that extends from zero (for a random point pattern) to

one (for perfect hexagonal packing), and as such, provides a sense along a finite continuum of where a mosaic is positioned. Like the regularity index, it is a scale-independent measure, allowing direct comparisons between mosaics across variation in density. But the packing factor is an index of packing, not regularity (e.g., square and hexagonal lattices have identical regularity indexes but differ in their packing), and exhibits only a weak correlation with regularity index (Figure 5(b)).

The relationships between nearest neighbor regularity index, Voronoi domain regularity index, effective radius, and packing factor across a twofold variation in density have recently been examined in a large sample of mosaic fields of horizontal cells in the mouse retina (Raven, M. A. *et al.*, 2005a). There, the correlation coefficient associated with the regularity index derived from a nearest neighbor analysis was always lower than that for the regularity index derived from the measure of Voronoi domain areas when correlated with any of the other features (density, packing factor, effective radius). Not surprisingly, the regularity indexes derived from nearest neighbor analysis and Voronoi domain analysis were positively correlated, but the fact that the former index is obtained by taking into account the relationship between each cell and only one of its neighbors produces a greater variance in the index that appears to be unrelated to the two-dimensional patterning of the mosaic.

1.22.2.4 Simulating the Distribution of Retinal Nerve Cells

Rather than model the mosaic upon a regular lattice that is distorted or jittered, others have sought to define the features that discriminate it best from a random distribution. Like a random simulation, most retinal mosaics yield autocorrelograms indicating that elements in the mosaic have no specific positional relationships beyond the stipulation that they do not encroach too closely upon one another, evidenced by the exclusion zone. In the case of the random mosaic, the size of the exclusion zone is defined by the soma size, while in the real mosaic, it is larger than this, being related to the average nearest neighbor distance. This, then, is the sole feature discriminating the autocorrelograms for these two conditions, despite the fact that the original mosaics are so qualitatively different with respect to the presence of patterning (Figure 4).

The minimal distance model is one such attempt to encapsulate this essence of the results derived from autocorrelation analysis. By specifying a minimal distance between the cells (the d_{min} rule, being some mean value and associated standard deviation) as they get added otherwise randomly to a simulation of given density (Figure 6, top), the simulated outcomes are often geometrically indiscriminable from their real mosaics (Figure 6, bottom). This approach has proven successful in replicating a variety of mosaics with great fidelity (Shapiro, M. B. *et al.*, 1985; Scheibe, R. *et al.*, 1995; Galli-Resta, L. *et al.*, 1997, 1999; Cellerino, A. *et al.*, 2000; Raven, M. A. *et al.*, 2003). Other variations on it have sought to encompass potential developmental mechanisms that might yield such minimal distance spacing rules, for instance, lateral inhibitory mechanisms that prevent cells of like-type from developing too close to one another (Cameron, D. A. and Carney, L. H., 2004; Tyler, M. J. *et al.*, 2005), selective cell-death mechanisms that eliminate neighboring cells of the same type (Eglen, S. J. and Willshaw, D.J., 2002), or mutual repulsion mechanisms that drive neighboring cells of the same type apart from one another (Eglen, S. J. *et al.*, 2000). Whatever the biological mechanism, or mechanisms, underlying it (Raven, M. A. *et al.*, 2005b), the minimal distance spacing rule provides a simple account of how homotypic interactions governing proximity can yield such biological patterning.

1.22.2.5 Functional Implications of Regular Retinal Mosaics

The assumed significance of such order in the distribution of various types of retinal nerve cell is that it ensures a relatively uniform contribution of each cell type in the local circuitry associated with visual analysis and so such patterning in retinal cell distributions has come to be taken for granted. Some examples, however, turn out to violate this expectation. For instance, the regularity in the patterning of rod photoreceptors in the ground squirrel's retina drops from 6.0 (e.g., Figure 2(a)) to approach 2.0 as rod density declines by about 80% from its peak value in the ventral retina (Galli-Resta, L. *et al.*, 1999); one would expect the rods to space themselves out as density declines to maintain a comparable order across such variation in density, as they generally do for other cell types. Rather, the rods maintain a fixed minimal spacing between themselves across variation in density, suggesting a developmental constraint upon their proximity rather than any functional constraint relating to

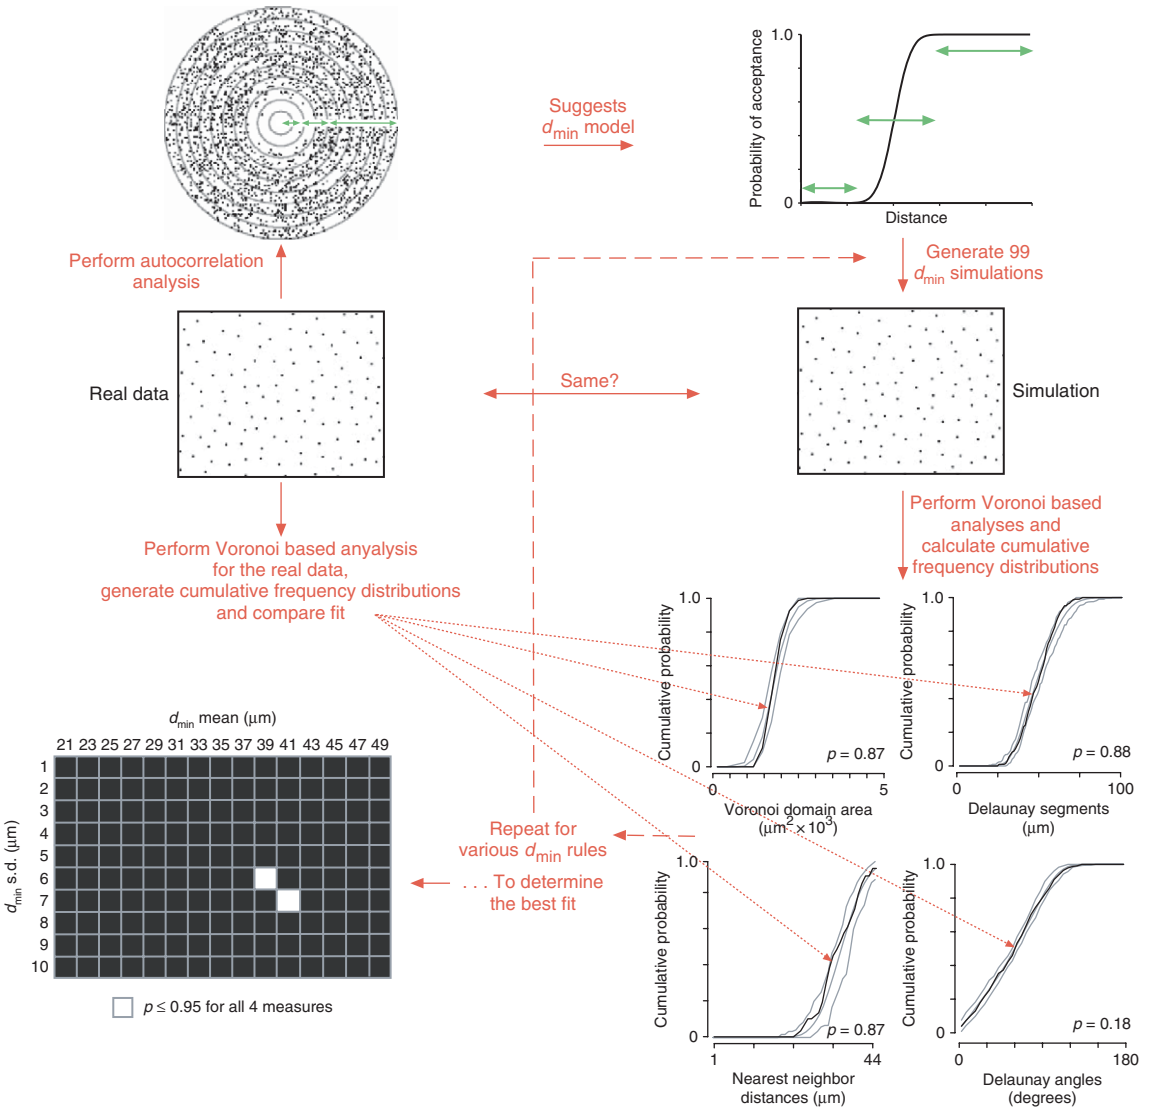

Figure 6 Modeling the mosaic using a minimal distance spacing rule. Top: the exclusion zone in the auto-correlogram indicates that neighboring cells avoid being positioned in close proximity. The minimal distance model (d_{min} model) stipulates a mean and standard deviation of minimal distances permissible in otherwise random simulations of cells generated sequentially. Ninety-nine simulations are generated, and each is compared with the original mosaic using Voronoi-based (or other) analyses. Bottom: a *p* value is assigned for the goodness of fit of the real mosaic relative to the simulations, shown here as cumulative frequency histograms, for each test. The entire process is repeated for slight variations in d_{min} mean and standard deviation (e.g., 150 d_{min} rules are shown for this example at lower left), to determine the best d_{min} rule simulating the mosaic. For the real mouse horizontal cell mosaic illustrated, only two d_{min} rules (39 ± 6 μm and 41 ± 7 μm) provided acceptable fits. Multiple fields are then tested, to examine the generality of the d_{min} rule, or to determine how it varies as a function of cell density or other features associated with the mosaic.

their orderliness (Reese, B. E. and Galli-Resta, L., 2002). The S cones in the ground squirrel's retina (Figure 2(b)), by contrast, show little variation in regularity across (a much smaller) variation in density, distributed in a pattern that is far more regular than achieved by random distributions, and assumed to reflect a greater functional benefit for photopic vision (Galli-Resta, L. *et al.*, 1999). But regularity in the S cone mosaic does not appear to confer any obvious functional benefit since other mammals show a striking variation in the extent to which S cone distributions deviate from random, particularly amongst the diurnal primates (deMonasterio, F. M. *et al.*, 1985; Ahnelt, P. K. *et al.*, 2000; Martin, P. R. *et al.*,

2000; Roorda, A. *et al.*, 2001). Whereas old world monkeys have regular distributions of S cones, the distribution in the human eye comes very close to being a random distribution (Martin, P. R. *et al.*, 2000; Roorda, A. *et al.*, 2001; Hofer, H. *et al.*, 2005) despite these species' comparable visual abilities.

The significance of such variation within photoreceptor mosaics remains to be determined. The contribution of photoreceptors to visual function is ultimately dependent upon their spatial distribution, given the punctate nature of their outer segments, but whether the critical feature is local density rather than patterning may depend upon the type of photoreceptor and the species in question. For other, postreceptoral, retinal cell types, their functional contribution to visual processing is associated with the distribution of their processes, and here, it is widely assumed that regular spacing between the cells increases the likelihood that the distribution of their processes will subserve the retinal surface uniformly. Indeed, the developmental constraints that produce such patterning in retinal neurons may also simplify the assembly of retinal connections during development (Galli-Resta, L., 2001), because such a population of cells may carry intrinsic instructions to grow a radially symmetric dendritic field of a specified size (Farajian, R. *et al.*, 2004; Lin, B. *et al.*, 2004). While this assumption may hold for some retinal cell types, it does not for many others where process growth is very much influenced by both homotypic neighbor-relationships and by relationships with afferents (Reese, B. E. *et al.*, 2005). These features associated with the morphology of the postreceptoral neurons, as they relate to retinal coverage, will be considered next.

1.22.3 Dendritic Coverage

1.22.3.1 Global Variation in Dendritic Field Size

Each type of postreceptoral retinal neuron exhibits its characteristic morphology across the retina, but with some variation in overall size as a function of the above global variations in cell density across eccentricity. Typically, the dendritic field of a given cell type increases with increasing eccentricity from the fovea, area centralis, or visual streak, coincident with the decline in density for that cell type. Figure 7 illustrates, for four different types of retinal cell, their increase in dendritic field size at progressively more eccentric locations upon the retina. Each displays unique morphological properties that remain discriminable as overall dendritic field size increases with eccentricity.

1.22.3.1.1 Dendritic overlap and the coverage factor

Figure 8(a) illustrates, for one such population, the A-type (axonless) horizontal cells in the cat retina, the change in dendritic field diameter as a function of eccentricity. Figure 8(b) shows the corresponding variation in A-type cell density across eccentricity (Wässle, H. *et al.*, 1978). That these two changes are related is made apparent by the fact that their product, dendritic field area × cell density (termed the coverage factor (Peichl, L. and Wässle, H., 1979)), is relatively constant across the retina (Figure 8(c)). These cells exhibit a constant dendritic overlap: on average, every location on the retina will be subserved by three to four dendritic fields for this cell type. A single cone pedicle, therefore (being the sole afferent to the horizontal cell dendrite), may contact up to four horizontal cells at every retinal locus. Similar trends hold for other retinal cell types, with dendritic field area increasing in proportion to the reduction in cell density, although a number of exceptions have been documented (Tauchi, M. and Masland, R. H., 1984; Mills, S. L. and Massey, S. C., 1991, 1994; Young, H. M. and Vaney, D. I., 1991; Wässle, H. *et al.*, 2000).

1.22.3.2 Variation in Dendritic Overlap between Retinal Nerve Cell Types

The coverage factor of a cell type is usually presumed to equal or exceed a value of 1, to ensure that no locations upon the retina are devoid of a contribution to the retinal circuitry by that cell type. But the coverage factors for different cell types differ markedly, ranging from 1 to >100, where such variation in field overlap is thought to reflect the distinct contributions of those different types of retinal cell to processing the retinal image.

1.22.3.2.1 Dendritic tiling and contact inhibition

A coverage factor of 1, then, indicates an average of one field overlying each location on the retinal surface, and coverages exceeding this slightly may indicate a consistent overestimate of the size of the dendritic field area. Of course, for circular dendritic field profiles to cover the retina completely, there must be some degree of overlap even if they are spaced as a regular hexagonal lattice, and so coverage factors in slight excess of 1 may simply reflect this

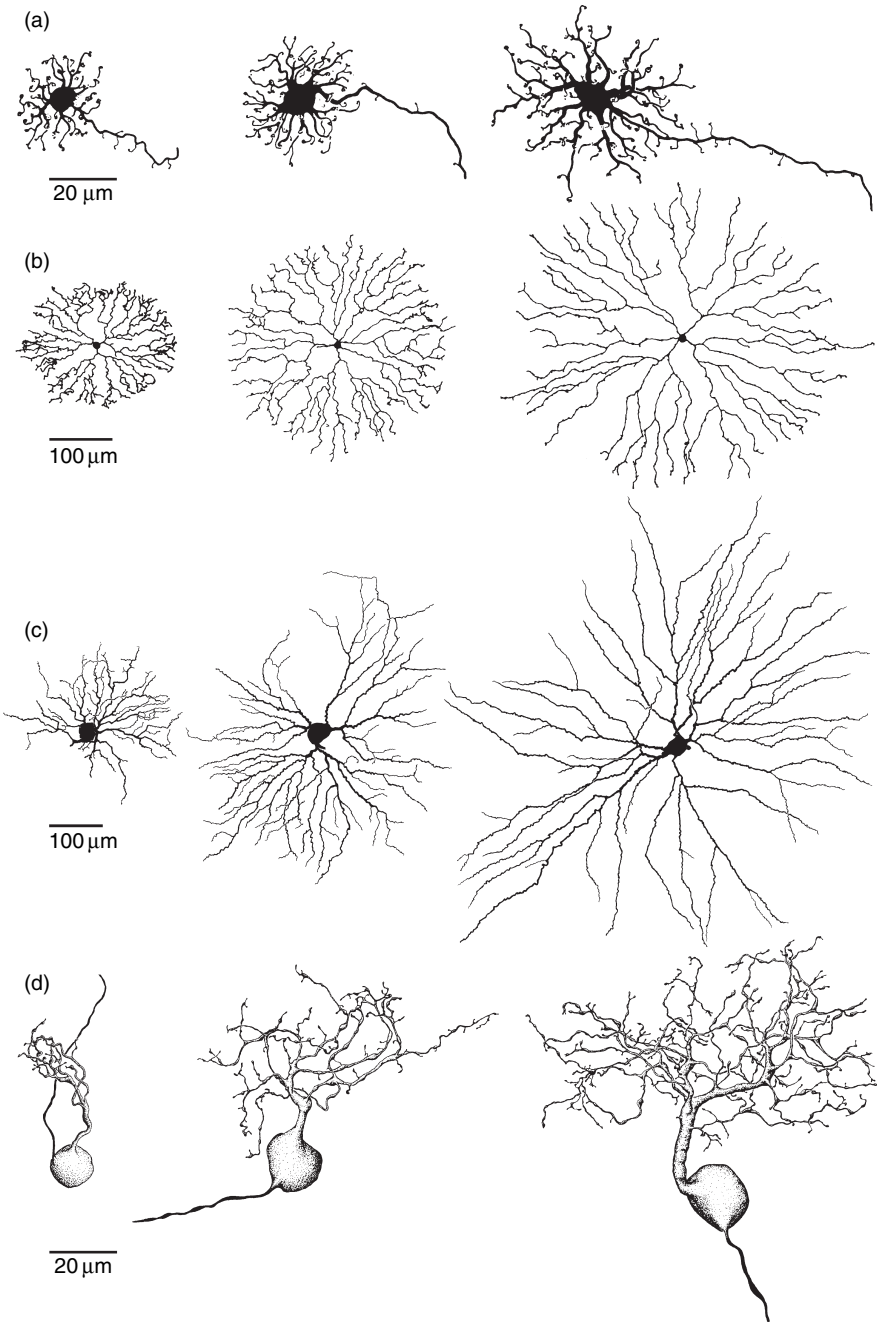

Figure 7 Increase in dendritic field size as a function of eccentricity: (a) H1 (axon-bearing) horizontal cells in the squirrel retina 1.7 mm, 4.3 mm, and 8.9 mm ventral to the visual streak; (b) cholinergic amacrine cells in the rabbit retina at the visual streak and 4 mm and 9 mm ventral to it; (c) alpha retinal ganglion cells in the cat retina 1 mm, 4 mm, and 10 mm from the area centralis; (d) midget retinal ganglion cells in the human retina at 2.5 mm, 6.5 mm, and 10 mm from the fovea. Figure 8 A-type (axonless) horizontal cell dendritic field diameter increases with eccentricity (a), while A-type cell density declines with eccentricity (b). The increase in dendritic field size compensates for the decline in density to maintain a constant dendritic coverage factor (dendritic field area × cell density) across the retinal surface (c). Adapted from Wässle, H., Peichl, L., and Boycott, B. B. 1978 Topography of horizontal cells in the retina of the domestic cat. Proc. R. Soc. Lond B. 203, 269–291, with permission from The Royal Society, London.

(Wässle, H. *et al.*, 1981b; Szmajda, B. A. *et al.*, 2005). Achieving a true uniform coverage of 1 requires a tiling of the retina by dendritic fields that extend right up to the boundary of the dendritic fields of adjacent cells, and by necessity cannot be circular profiles. That dendritic fields may modulate their growth in relation to the presence of neighboring homotypic dendritic fields had been suspected for some time, given the fact that they are often irregular rather than circularly symmetric around the soma. Consistent with this, the geometry of their dendritic

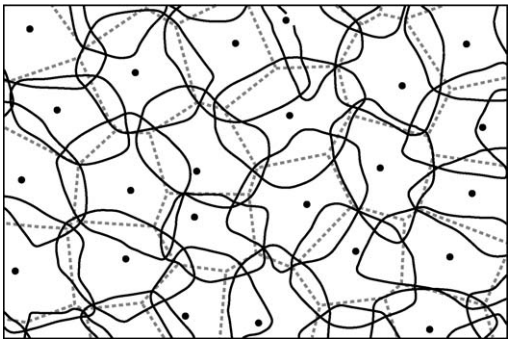

Figure 9 Mosaic of ON-alpha ganglion cell dendritic fields in the cat retina outlined in smooth contours to encircle the dendrites, plotted relative to their somatic positioning. The Voronoi domains associated with those somata are also illustrated, showing that dendritic field shape is constrained by proximity to homotypic neighbors. Adapted by permission from Macmillan Publishers Ltd: Nature, Wässle, H., Peichl, L., and Boycott, B. B. 1981c. Dendritic territories of cat retinal ganglion cells. Nature 292, 344–345, copyright 1981.

field shapes sometimes correlates with proximity to their Voronoi neighbors (Figure 9) (Wässle, C. *et al.*, 1981c). Dendritic field size and shape also undergo compensatory changes in response to early experimental manipulations that alter neighbor relationships (Perry, V. H. and Linden, R., 1982; Eysel, U. T. *et al.*, 1985; Kirby, M. A. and Chalupa, L. M., 1986). More recent studies eschewing the traditional means of estimating dendritic field size by constructing convex polygons or smooth closed outlines (Wässle, C. *et al.*, 1981c; 1989; Watanabe, M. and Rodieck, R. W., 1989) have attempted to assign precise concave profiles to the irregular boundaries associated with neighboring ganglion cell dendritic fields (Dacey, D. M., 1993; Szmajda, B. A. *et al.*, 2005), reporting the boundaries between adjacent midget retinal ganglion cells to be coincident, establishing minimal overlap, as should be expected for a perfect tiling of the retinal surface (Figure 10; see also Vaney, D. I., 1994; Amthor, F. R. and Oyster, C. W., 1995).

Given this evidence, the variation in dendritic field size across eccentricity might be thought to reflect active growth constrained by homotypic neighbor relationships, rather than a consequence of passive interstitial dendritic growth produced by greater expansion of the peripheral retina (Hitchcock, P. F. and Easter, S. S., 1986; Wong, R. O. L. and Collin, S. P., 1989; Rodieck, R. W. and Marshak, D. W., 1992). Likewise, while much of the published variation in dendritic field size for cells at a given eccentricity has been ascribed to differences in cell density along different retinal axes, a twofold variation in dendritic field

size is present even within the same patch of retina (Figure 10), consistent with the local variability in the size of Voronoi domains found in regular retinal mosaics (Figures 4 and 9). These studies support the notion that a simple developmental mechanism, that of contact-inhibition between the dendrites of homotypic neighbors, creates the tiling characteristic of such retinal mosaics.

1.22.3.2.2 Regulating dendritic overlap by homotypic interactions

For retinal mosaics with coverage factors greater than 1, it is unlikely that they require the same precision in their uniformity of coverage afforded by the above mechanism. Some cell types, for example, the horizontal cells (Figure 7(a)), have coverage factors in the region of 3–8 (Wässle, H. *et al.*, 1978; Mills, S. L. and Massey, S. C., 1994) that are reasonably (though not always) well preserved across marked variation in cell density. Such unchanging coverage could occur secondarily if dendritic growth was intrinsically specified, and passive (interstitial) growth driven by retinal expansion then diluted cell density in the more peripheral parts of the retina. This explanation cannot, however, account for the modulation of dendritic field size in horizontal cells in different strains of mice (Reese, B. E. *et al.*, 2005); there, in the absence of any appreciable variation in total retinal size, horizontal cell morphology is scaled accordingly to maintain constant coverage across a twofold variation in horizontal cell density between the strains (Figure 11). As predicted from these correlational studies, genetic manipulations that directly modulate horizontal cell density also produce corresponding changes in dendritic field size (Reese, B. E. *et al.*, 2006). These results are consistent with those considered above indicating that dendritic growth is constrained by homotypic neighbors, even if a simple contact-inhibition at the tips of dendrites is insufficient to explain the coverages obtained. The same may prove to be the case for some other cell types

Figure 10 Mosaic of ON-midget ganglion cell dendritic fields in the periphery of the human retina. Dendrites from adjacent cells share common boundaries without overlap, establishing a precise tiling of the retinal surface. Adapted from Dacey, D. M. 1993 The mosaic of midget ganglion cells in the human retina. J. Neurosci. 13, 5334–5355, Copyright 1993 by the Society for Neuroscience, with permission.

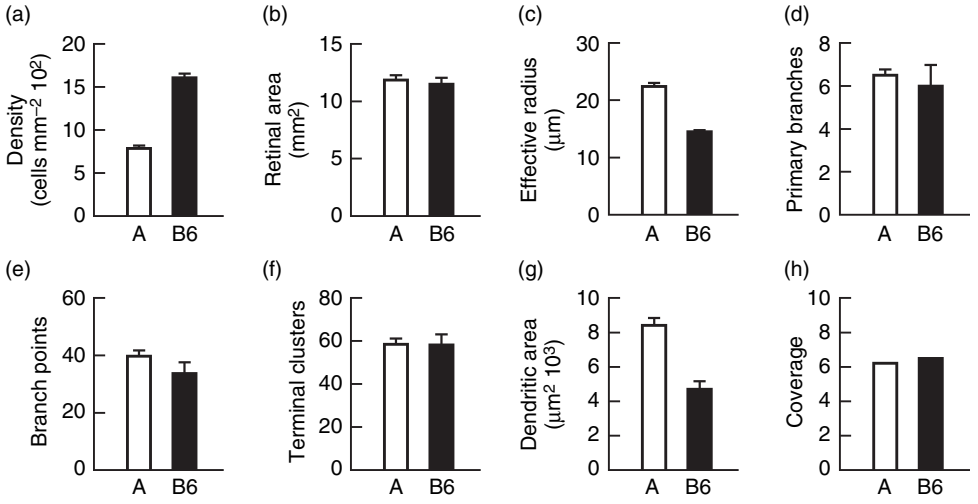

Figure 11 B-type (axon-bearing) horizontal cells in the C57BL/6J and A/J mouse retinas show a nearly twofold density difference (a) despite comparable retinal areas between the strains (b). They show a corresponding variation in the size of their effective radius, minimizing proximity between neighboring horizontal cells (c). These cells differentiate comparable dendritic morphologies (d–f), but modulate their overall dendritic field size (g) to maintain a constant dendritic coverage (h). Adapted from Reese, B. E., Raven, M. A., and Stagg, S. B. 2005 Afferents and homotypic neighbors regulate horizontal cell morphology, connectivity and retinal coverage. J. Neurosci. 25, 2167–2175, Copyright 2005 by the Society for Neuroscience, with permission.

with coverage factors in this range (Wässle, H. *et al.*, 1981a; Mills, S. L. and Massey, S. C., 1991; Vaney, D. I. *et al.*, 1991; Young, H. M. and Vaney, D. I., 1991).

1.22.3.2.3 Overlap unregulated by homotypic interactions?

Other types of retinal cell have coverage factors an order of magnitude greater than this. Perhaps the most widely studied is the cholinergic amacrine cell (Figure 7(b)), the coverage factor of which has been estimated to be as great as 70, depending upon the species (Tauchi, M. and Masland, R. H., 1984; Famiglietti, E. V., 1985; Schmidt, M. *et al.*, 1985; Voigt, T., 1986; Rodieck, R. W. and Marshak, D. W., 1992; Sandmann, D. *et al.*, 1997). Given such coverage, these cells should have ample opportunity to interact homotypically, particularly as their dendrites fasciculate together and exchange synaptic contacts (Tauchi, M. and Masland, R. H., 1985; Brandon, C., 1987; Lee, s. and Zhou, Z. J., 2006). Yet partially depleting this population of cells by 40% during early development, well before adult coverage is obtained, does not alter the dendritic field of the remaining cells, which continue to differentiate a normal adult morphology and size (Farajian, R. *et al.*, 2004). These cells behave as if their dendritic growth is controlled by cell-intrinsic mechanisms rather than by homotypic interactions. This strategy would seem increasingly likely for the various widefield amacrine cell types, where process growth is often vast, yet extremely sparse (Vaney, D. I., 1986, 2004; Dacey, D. M., 1990).

One would envision the need for precision in coverage to be related to retinal cell types associated with the creation of center-surround receptive fields employed in the transmission of the retinal image, rather than with other cell types modulating those radial pathways. Dopaminergic amacrine cells give rise to sparsely distributed dendritic and axon-like processes mostly restricted to a narrow stratum of the inner plexiform layer, yet dopamine acts upon receptors with a far broader distribution across the retina (Veruki, M. L. and Wässle, H., 1996) and its release is modulated extrasynaptically (Puopolo, M. *et al.*, 2001). Like retinal horizontal cells in the mouse, this cell class displays a large (threefold) variation in cell number between different strains (unpublished observations), but might establish a comparable functional contribution not by modulating field size in proportion to cell density, as in the case of the horizontal cells, but by modulating the release of dopamine (Puopolo, M. *et al.*, 2001). It is conceivable that the growth of the dopaminergic dendritic versus axonal processes is controlled independently, given their difference in estimated retinal coverage (3 vs. 300; Voigt, T. and Wässle, H., 1987; Dacey, D. M., 1990; see also Dacey, D. M., 1989), but a low coverage factor should not be taken to necessitate homotypic regulation of growth. Even certain classes of retinal ganglion cells with limited dendritic overlap may achieve their dendritic fields independent of neighbor-interactions, for instance, the melanopsin-containing ganglion cells that transmit information about the circadian variation in retinal luminance (Lin, B. *et al.*, 2004). Not surprisingly then, these very cell types have regularity indexes that are just marginally better, or no better, respectively, than matched random simulations (Raven, M. A. *et al.*, 2003; Semo, M. *et al.*, 2005). For the latter cell type, one might even conceive little benefit to having a minimal coverage of 1, since neither uniform nor complete retinal coverage would appear relevant for the detection of circadian changes in photic environment (see Chapter Melanopsin Cells). (In primates, at least, this cell type also receives synaptic input arising from photoreceptors in the outer retina, transmitting spatial information as well, and so may prove to be more regular in its cellular distribution and achieve a more uniform coverage than in other species; Dacey, D. M. *et al.*, 2005).

1.22.3.3 Dendritic Coverage and Connectivity

While the calculation of a coverage factor provides an index of the degree to which neighboring cells of the same type overlap one another, and may therefore intimate aspects of their functional contribution to retinal processing, coverage factors by themselves can be misleading, because the dendritic fields do not simply form overlapping blankets of processes of uniform density across the entire field. For instance, the density of higher order dendritic branching is not always uniform across the dendritic field (Figure 7(d)), such that regions of high- and low-branch frequency yield territories of dendritic clustering within the field of peripheral midget retinal ganglion cells in old world primates (Dacey, D. M., 1993). The significance of this clustering and its relationship to both afferent input and the sensitivity profile of the receptive field remain to be defined (Dacey, D. M., 1993; Brown, S. P. *et al.*, 2000; Jusuf, P. R. *et al.*, 2006) (see Chapter The P, M, and K Streams of the Primate Visual System: What Do They Do for Vision?). The cholinergic amacrine

cells, by contrast, are far more radially symmetrical in their dendritic morphology (Figure 7(b)) where an outer annulus of the field is defined by beaded presynaptic terminals, while synaptic inputs are formed throughout the field (Famiglietti, E. V., 1991). The processes of cholinergic amacrine cells fasciculate with one another within the inner plexiform layer yielding a lattice enclosing lacunae devoid of cholinergic processes (Tauchi, M. and Masland, R. H. 1985). There, they also fasciculate with the dendrites of direction-selective retinal ganglion cells, bestowing upon the latter their direction selectivity by virtue of the cholinergic dendrites being themselves directionally selective (Euler, T. *et al.*, 2002), releasing both GABA and acetylcholine to modulate different sets of directionally selective ganglion cells within a region of the cholinergic matrix (Taylor, W. R. and Vaney, D. I., 2003) (see Chapter Direction-Selective Cells). Indeed, given the local processing associated with different sectors of the dendritic field (Lee, S. and Zhou, Z. J., 2006), the functional coverage of this cell type may more closely approximate a factor of 2. The dendritic terminals of horizontal cells are punctate in their distribution within the dendritic field (Figure 7(a)) in association with their afferents, the cone pedicles (Ahnelt, P. and Kolb, H., 1994b). Furthermore, the number of dendritic terminal contacts per pedicle decreases as a function of increasing distance from the center of the dendritic field (Ahnelt, P. and Kolb, H., 1994a; Reese, B. E. *et al.*, 2005), so that, while each cone pedicle may be contacting an equivalent number of horizontal cells, its effect upon them is by no means equivalent. Horizontal cells are also electrically coupled via gap junctions, expanding their functional domain well beyond the limits of the dendritic field, and rendering the dendritic coverage factor functionally irrelevant in the coupled condition (Bloomfield, S. A. *et al.*, 1995; Packer, O. and Dacey, D. M., 2005) (see Chapter Contributions of Horizontal Cells). Finally, for those widefield amacrine cells that give rise to a few thin varicose processes extending for millimeters upon the retinal surface, while these cells have ample overlap evidenced by the crisscrossing of processes from adjacent cells, a simple calculation of their field area multiplied by cell density grossly overestimates the local density of processes upon the retinal surface (Dacey, D. M., 1990; Vaney, D. I., 2004) (see Chapter Amacrine Cells). Future studies integrating other measures of dendritic complexity and process density, for example, Sholl analysis (Sholl, D. A., 1953) in conjunction with cell density measures, would provide a richer appreciation of the retinal coverage of an individual cell type.

1.22.4 Conclusions

The positioning of a neuron within the plane of the retinal surface, like the distribution of its processes, is, for many types of retinal cell, dependent upon homotypic relationships. Other cell types show less obvious homotypic dependency, suggesting that the developmental mechanisms creating this patterning and process overlap are quite distinct. How these mosaics are assembled during development, and the nature of those cell intrinsic and environmental signals governing process outgrowth, target recognition and synapse formation are increasingly the focus of attention as we try to understand the construction of those features of the retinal circuitry that ultimately underlie the functional contribution of each cell type. Similar questions can be asked of neurons within the brain, where little is known about the constraints upon neuronal positioning in three dimensions, and even less about the coverage associated with their dendritic fields. As the biological and (more critically) software tools become available, the understanding of the three-dimensional spatial relationships between neurons will come to the forefront, enhancing our appreciation of the relationship between form and function at the population level.

1.23.1 Gap Junctions

Although chemical neurotransmission is the dominant means of communication between neurons, it is clear that electrical synapses, known as gap junctions, occur frequently and they are physiologically significant (Galarreta, M. and Hestrin, S., 2001). Gap junctions are named after the narrow gap between two closely apposed cell membranes. They are composed of two docked hemichannels, or connexons, each of which is built from six connexins surrounding a central pore (Figure 1). This pore forms an intercellular channel between the connected cells that allows the passage of ions and small molecules up to a molecular weight of approximately 1000. Each connexin spans the cell membrane four times. There are two extracellular loops, which are conserved and thought to be involved with docking between two adjacent cells to form a gap junction. In addition, there is one intracellular loop and both the N- and the C-terminals are cytoplasmic. These sites may be available for biochemical modulation. The intracellular loop and C-terminal sequences are commonly used to raise antibodies.

Approximately, 20 different connexins have been identified and this diversity is thought to underlie the functional properties of different gap junctions such as permeability, gating, voltage dependence, and modulation (Willecke, K. *et al.*, 2002; Menichella, D. M. *et al.*, 2003). In the retina, gap junctions in different cell types have distinct properties. For example, different gap junctions are selectively permeable to different dyes or tracers and they are differentially modulated by various signaling molecules such as cAMP and cGMP (Mills, S. L. and Massey, S. C., 1995; 2000). Thus, it appears multiple neuronal connexins are expressed in the mammalian retina and it has recently become clear that different cell types express specific neuronal connexins. Furthermore, gap junctions play specific and important functional roles in retinal circuitry.

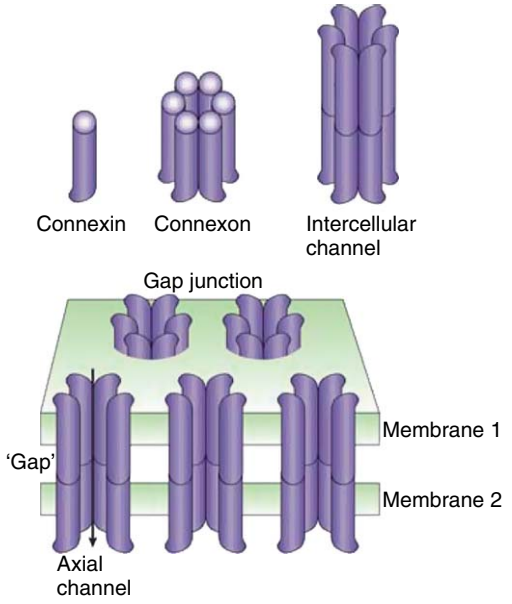

Figure 1 Gap junctions function as electrical synapses. They are constructed from membrane spanning proteins called connexins. Six connexins form a connexin, or hemichannel, and two connexins dock to form a gap junction, an intercellular pore between adjoining cells. Gap junctions are arranged in plaques, two-dimensional arrays that may contain many single channels. From Goodenough, D. A. and Paul, D. L. 2003. Beyond the gap: functions of unpaired connexin channels. Nat. Rev. Mol. Cell Biol. 4, 285–294.

From this family of twenty or so connexins, only four, Cx36, Cx45, Cx50, and Cx57 have so far been found in mammalian neurons and we will refer to these as neuronal connexins. Importantly, some additional homologs have been reported in fish retina (Shields, C. R. *et al.*, 2005; O'Brien, J. *et al.*, 2004). Connexin 36 is the dominant neuronal connexin and it is found in all cell types except horizontal cells (HCs) (Deans, M. R. and Paul, D. L., 2001; Feigenspan, A. *et al.*, 2001; Mills, S. L. *et al.*, 2001; Deans, M. R. *et al.*, 2002; Lee, E. J. *et al.*, 2003; Feigenspan, A. *et al.*, 2004). Recent data suggest that Cx50 and Cx57 are expressed in different types of HC (Massey, S. C. *et al.*, 2003; Hombach, S. *et al.*, 2004). In addition, Cx45 has also been found in mammalian retina in bipolar cells, amacrine cells, and ganglion cells (Guldenagel, M. *et al.*, 2000; Maxeiner, S. *et al.*, 2005).

Historically, gap junctions have been difficult to visualize. They are small and easily overlooked in electron micrographs but they present a distinctive profile in freeze–fracture preparations (Raviola, E. and Gilula, N. B., 1973; Kamasawa, N. *et al.*, 2006). Until recently, the connexin antibodies have been unreliable but this is rapidly improving. As the various neuronal connexins are identified and specific antibodies are developed, this may become the method of choice to identify gap junctions in neural networks.

The transfer of small tracers such as Neurobiotin can also reveal gap junction coupling and this type of experiment shows specific coupling patterns, often between cells of the same type, but also in complex heterocellular pathways such as the AII/cone bipolar network (Vaney, D. I., 1991). The use of other fluorescent dyes, particularly Lucifer Yellow, for visualizing coupled neurons must be interpreted very cautiously because many, or perhaps most, neuronal gap junctions do not pass Lucifer Yellow. A stunning exception to this rule is provided by A-type HCs in the rabbit retina, which are permeable to Lucifer Yellow. This also indicates that HC gap junctions are probably different from those of other retinal neurons (Dacheux, R. F. and Raviola, E., 1982). HCs in the fish retina also have gap junctions which pass Lucifer Yellow (Teranishi, T. *et al.*, 1983).

1.23.2 Clinical Relevance

Gap junctions also have potential clinical significance. Mutations in connexin genes underlie several genetic diseases including Charcot–Marie–Tooth disease, a peripheral myopathy due to demyelination, thought to result from the absence of Cx32 gap junctions which permit the diffusion of nutrients and metabolites in spiral structures (Menichella, D. M. *et al.*, 2003). Cx46 and Cx50 mutations cause congenital cataracts, Cx26 mutations are associated with deafness and Cx40 and Cx43 knockout mice have cardiac abnormalities (Willecke, K. *et al.*, 2002; Menichella, D. M. *et al.*, 2003). Given the prevalence of gap junctions in the retina, it seems likely that a connexin mutation could cause a visual defect, perhaps in the photoreceptor matrix or in rod pathways.

Gap junctions have also been implicated in photoreceptor degeneration via a mechanism known as the bystander effect. It has been proposed that dying rods transmit a signal to cones via gap junctions, spreading cell death in retinitis pigmentosa (Ripps, H., 2002; Cusato, K. *et al.*, 2003). In addition, in a model of cell death due to stroke, it has been suggested that one of the final terminal events is the opening of hemichannels in the cell membrane. This produces a profound

disruption of ionic balance, a ubiquitous component of ischemic neuronal death (Thompson, R. J. *et al.*, 2006).

1.23.3 Functional Roles for Gap Junctions in the Retina

Gap junctions are common in the central nervous system (CNS) but they seem to be particularly abundant in the retina. This may be the case because signal averaging and noise reduction are important strategies in the early steps of visual processing. Here, we will provide four examples from the retina where gap junctions appear to serve a specific function: photoreceptor coupling, HCs, the AII amacrine cell network, and ganglion cell coupling.

1.23.3.1 Photoreceptors

There are two kinds of photoreceptor in the mammalian retina. Cones support color vision under relatively bright conditions and, in central retina or the primate fovea, they are densely packed, to the exclusion of rods, to support the highest acuity. Rods are much more numerous, except in central retina, and they have increased sensitivity to function in low light conditions. There is an understandable tendency to think of rod and cone pathways as separate and distinct but in fact rod/cone coupling provides a pathway for substantial mingling of rod/cone signals.

1.23.3.1.1 Cone-to-cone coupling

Classic ultrastructural studies revealed small gap junctions between cones, as well as between cones and rods in mammals, including primate (Raviola, E. and Gilula, N. B., 1973; Kolb, H., 1977; Ahnelt, P. K. and Pflug, R., 1986; Tsukamoto, Y. *et al.*, 1992; Tsukamoto, Y. *et al.*, 2001). This is supported by tracer injections that show dye coupling between neighboring cones in several mammalian species (Hornstein, E. P. *et al.*, 2004; Li, W. and DeVries, S. H., 2004). At the base of each cone pedicle, there are fine processes, known as telodendria, which reach out to contact adjacent cones. In central retina, where the cone pedicles form a tightly packed array, the telodendria are necessarily short but in peripheral retina they extend further (Figure 2). The contact points between telodendria and adjacent cones are the sites of gap junctions with neighboring cone pedicles or intervening rod spherules.

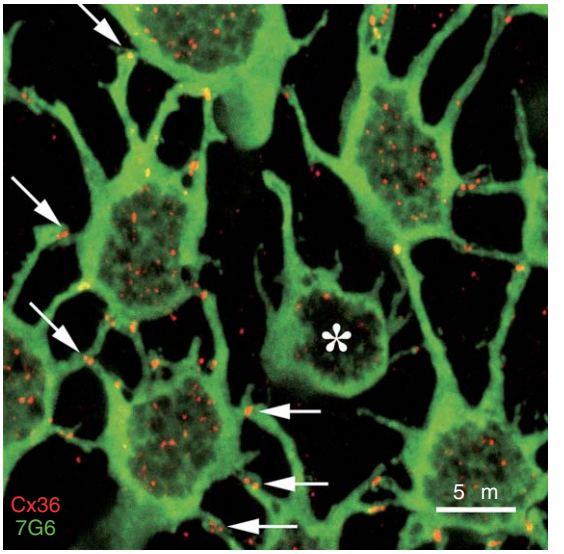

Figure 2 Connexin 36 gap junctions between the telodendria of cone pedicles, stained with an antibody against cone arrestin (7G6, green), in the outer plexiform layer of macaque retina. Some Cx36 gap junctions (red) at telodendrial contacts between adjacent cone pedicles are marked with arrows. The smaller cone pedicle, marked by an asterisk, is a blue cone pedicle with relatively few short telodendria. In contrast to red/green cones, the blue cone pedicles make few or no gap junctions with adjacent cones. Image courtesy of Jennifer O'Brien and Stephen C. Massey.

Small Cx36 plaques occur precisely at the contact points between telodendria and adjacent cones in the primate and ground squirrel retina (Figure 2) (Li, W. and DeVries, S. H., 2004). We have learned that this pattern, when Cx36 plaques occur at contact points, is diagnostic for gap junction labeling and similar to the pattern reported at dendritic crossings and intersections in the AII matrix (Mills, S. L. *et al.*, 2001). Thus, this result indicates that cone-to-cone coupling is mediated by Cx36 gap junctions and the network of telodendria forms the substrate for photoreceptor coupling. Punctate Cx36 labeling is found in the outer plexiform layer of all mammalian species and it is associated with cones (Feigenspan, A. *et al.*, 2004). The staining is fainter and the individual plaques are smaller than those on the AII matrix in the inner retina. A cluster of Cx36 labeling is also found under each cone pedicle, where incoming dendrites converge. Because HCs do not express Cx36, these gap junctions probably occur between bipolar cell dendrites before they contact the cone pedicle (Feigenspan, A. *et al.*, 2004).

Technically impressive dual recordings have established that adjacent cones in ground squirrel and

primate retina are electrically coupled (DeVries, S. H. *et al.*, 2002; Hornstein, E. P. *et al.*, 2004; Li, W. and DeVries, S. H., 2004). Coupling is bidirectional with a conductance of a few hundred picosiemens. Phototransduction is inherently noisy and cone-to-cone coupling improves the signal-to-noise ratio by correlating shared light-driven signals while random noise from each cone is reduced by averaging between adjacent cones across the network (DeVries, S. H. *et al.*, 2002). The small loss of spatial acuity as a result of coupling is apparently less than the optical blur of the eye. It has been calculated that cone-to-cone coupling results in a 70% increase in the signal-to-noise ratio.

1.23.3.1.2 Blue cones are not coupled to surrounding cones

Old World primates such as macaque are trichromatic with long, medium, and short wavelength-sensitive cones (red, green, and blue cones) (Baylor, D. A. *et al.*, 1987). It is not possible to discriminate morphologically between red and green cones but blue cones can be labeled with an antibody against blue cone opsin. Blue cones also have smaller pedicles with few telodendria (Figure 2) (Ahnelt, P. *et al.*, 1990). The ground squirrel, which has amenably large cones suitable for recording, and most other mammals have only green and blue cones. Red/green cones, in primate, or green cones in ground squirrel are dye coupled but the small minority of S cones, approximately 10%, are not coupled to the other cones. This has been directly confirmed by paired recordings which show that electrical coupling between red/green or green cones is bidirectional but, in both species, blue cones are isolated from surrounding cones (Hornstein, E. P. *et al.*, 2004; Li, W. and DeVries, S. H., 2004) The telodendria of blue cone pedicles are short and there are few or no Cx36 contacts with adjacent cone pedicles (Figure 2). These results are consistent: dual recording, dye coupling, and Cx36 labeling all indicate that blue cone pedicles are not coupled to the other cones. Cone-to-cone coupling leads to an increase in sensitivity but there is a concomitant loss in spectral discrimination. Calculations show this is minor between red and green cones because their spectral curves are so close together (Hornstein, E. P. *et al.*, 2004). Patchiness, or the random distribution of cones, may also minimize this loss (Hsu, A. *et al.*, 2000). Conversely, the blue absorption curve is far removed from the red/green curves. Thus, blue cones may be uncoupled to preserve spectral discrimination (Hsu, A. *et al.*, 2000; Hornstein, E. P. *et al.*, 2004; Li, W. and DeVries, S. H., 2004).

1.23.3.1.3 Rod-to-cone coupling

In EM preparations, small gap junctions have been observed between rod spherules and cone pedicles (Raviola, E. and Gilula, N. B., 1975; Smith, R. G. *et al.*, 1986). Cones and rods are also dye coupled (Hornstein, E. P. *et al.*, 2005). Thus, signals bearing a rod signature can be recorded in cones and in HCs that are exclusively connected with cones (Nelson, R., 1977; Schneeweis, D. M. and Schnapf, J. L., 1995; 1999; Hornstein, E. P. *et al.*, 2005). Furthermore, rod-to-cone transmission occurs at intensities when cone phototransduction can be expected to make a minimal contribution. In immunolabeled material, there are many Cx36 plaques around the perimeter of each cone pedicle, often on fine telodendria that do not reach adjacent cones (Figure 3). These gap junctions are aligned with the surrounding rod spherules and form the substrate for rod-to-cone coupling. It appears that almost every rod spherule is connected to a nearby cone pedicle. While the evidence for the expression of Cx36 in cones is convincing, the identity of the rod connexin is currently unknown. The extent of Cx36 expression in the outer nuclear layer (ONL) first suggested that both rods and cones could use Cx36 (Deans, M. R. *et al.*, 2002). However, in the mouse retina, Cx36 appears to be restricted to cones (Feigenspan, A. *et al.*, 2004) and at rod/cone gap junctions in the guinea pig retina, Cx36 labeling is located on the cone side of the gap junction (Lee, E. J. *et al.*, 2003). Thus, it is possible that rod-to-cone gap junctions are heterotypic with Cx36 only on the cone side.

Rod/cone coupling provides an alternative pathway for rod signals to enter cone pathways at intermediate light intensities such as twilight conditions (Smith, R. G. *et al.*, 1986). At threshold or starlight levels, the high-gain rod pathway via rod bipolar cells is operational. Around 30–100 rods have input to each rod bipolar cell, dependent on species, and this convergence means that only one or two rods need to absorb a photon to produce a threshold signal. If only a small number of rods are excited, then there will be insufficient signal to influence adjacent cones via gap junctions.

However, at light intensities above approximately 2.5 photons per rod, the rod bipolar cell response is saturated (Dunn, F. A. *et al.*, 2006). At these mesopic intensities, there is enough light to stimulate many rods simultaneously while the cone signals are still close to threshold. Thus, the combined rod signals may provide a substantial input to cones (Hornstein, E. P. *et al.*, 2005). At still higher light

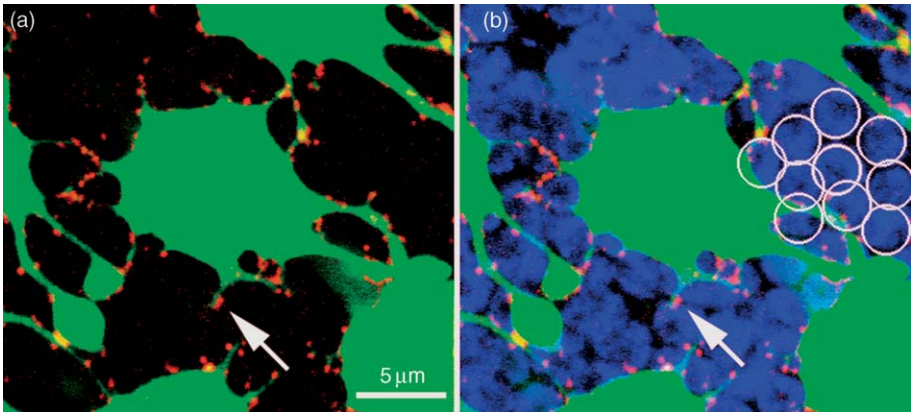

Figure 3 (a) A high-resolution image of cone pedicles, stained with an antibody against cone arrestin (green). Some of the telodendria are short and do not reach adjacent cone pedicles yet they still bear many small Cx36 plaques (red). (b) Same frame, showing rod spherules labeled with an antibody against the synaptic vesicle protein SV2B. Rod spherules appear as circular structures with a vesicle poor dark spot, often in the center, that corresponds to the synaptic invagination. Some examples of rod spherules are circled. Cx36 plaques on short telodendria are aligned with surrounding rod spherules and an example is marked with an arrow. These gap junctions are the substrate for rod/cone coupling. Image courtesy of Jennifer O'Brien and Stephen C. Massey.

intensities, the rod system is saturated but there is enough light to drive cones effectively. Thus, gap junctions between rods and cones are essential at intermediate light levels during the transition from rod-to-cone vision. It has long been suggested that rod/cone coupling should be variable so that at low light levels, the gap junctions are closed and single rod responses are not dissipated by the network (Smith, R. G. *et al.*, 1986).

1.23.3.1.4 Rod-to-rod coupling

Finally, in the mouse retina there are also gap junctions between rod spherules and tracer coupling has been reported between rods in the primate retina (Tsukamoto, Y. *et al.*, 2001; Hornstein, E. P. *et al.*, 2005). Under high scotopic conditions, this may improve performance in the high-gain rod pathway by delaying saturation of the rod bipolar cell response. However, rod-to-rod coupling may also increase the threshold for the very dimmest signals (Hornstein, E. P. *et al.*, 2005). If rod-to-rod gap junctions can also be modulated, then at threshold conditions they should be closed to maximize the response in a single rod. As more light is available, averaging between rods via open gap junctions would then be useful to extend the range of the rod pathway by preventing saturation of the rod bipolar response. There is no evidence yet that this occurs but it serves as an example for how gap junction plasticity can provide the best of both worlds in neural circuits.

1.23.3.2 Horizontal Cells

HCs are second-order, laterally extensive interneurons that provide negative feedback to cones in the outer retina and subtract a large, slow version of the visual scene. This is the basis for center surround antagonism, a common strategy in sensory systems, which helps to differentiate small, low-contrast signals against a common background (Wässle, H., 2004). HCs are much larger than cones and they are also famously connected via gap junctions into an extensively coupled network (Raviola, E. and Gilula, N. B., 1975; Kolb, H., 1977; Vaney, D. I., 1991; Mills, S. L. and Massey, S. C., 1994). Thus, the size of the receptive field far exceeds the extent of the dendritic field. This can be remarkable. For example, in the rabbit retina, the receptive field of A-type HCs is 20 times greater than the size of the dendritic field. Thus, the spatial extent of the feedback signal to cones is determined, in part, by the strength of coupling in the HC network (Dacheux, R. F. and Raviola, E., 1982; Bloomfield, S. A. *et al.*, 1995). In other words, the diameter of HC feedback can be changed according to factors, such as light adaptation, that modulate gap junction coupling between HCs. This is a good example of network plasticity and perhaps

the fundamental reason for gap junction coupling between HCs.

In the rabbit retina, there are two types of HC, which have different coupling properties (Dacheux, R. F. and Raviola, E., 1982; Mills, S. L. and Massey, S. C., 1994). Dye injections reveal that A-type HCs are extremely well coupled, allowing the passage of both Lucifer Yellow and Neurobiotin (Figure 4) (O'Brien, J. J. *et al.*, 2006). These are the only gap junctions in the rabbit retina that pass Lucifer Yellow. Dye injection of an A-type HC with Neurobiotin, which is much more permeable than Lucifer Yellow, yields thousands of dye-coupled A-type HCs in sheets that can stretch for millimeters across a wholemount retina. In contrast, B-type HCs are only permeable to Neurobiotin (Figure 4) (Vaney, D. I., 1993; Mills, S. L. and Massey, S. C., 1994). This immediately suggests that the two HC networks use different connexins.

1.23.3.2.1 A-type horizontal cells and Cx50

A-type HCs can be readily labeled either with an antibody against calbindin or, with more detail, by Neurobiotin injections. Double labeling with an antibody that recognizes Cx50 produced extensive labeling completely restricted to the A-type matrix (O'Brien, J. J. *et al.*, 2006) (Figure 5). The Cx50 labeling is coded green but in this image Cx50 plaques appears almost exclusively yellow because they only occur on A-type HC dendrites. Where large primary dendrites cross, there are often giant Cx50 plaques with irregular or polygonal shapes. The Cx50 plaque in the center of Figure 5 measures 63 μm^2 and must contain hundreds of thousands of gap junction channels. Cx50 channels have a high unitary conductance, 220 pS (Srinivas, M. *et al.*, 1999) so even if a large fraction of the gap junction channels are closed, our calculations suggest that the transjunctional resistance across such a giant plaque may be less than half a megaohm. The holes in the center of this plaque may indicate gap junction recycling and turnover. In addition, there are a large number of smaller Cx50 plaques spread throughout the A-type HC matrix including even the finest dendrites. Close inspection reveals that Cx50 plaques occur when dendrites cross or cofasciculate and this is the pattern expected for gap junction labeling. The numerous Cx50 plaques between the dendrites of A-type HC suggest that Cx50 gap junctions may adequately account for the remarkable coupling observed in this network.

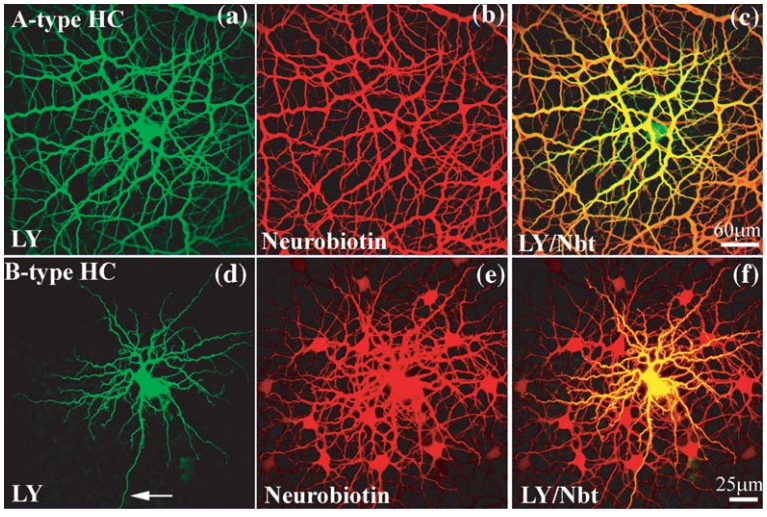

Figure 4 Differential tracer coupling of A- and B-type horizontal cells (HCs) in the rabbit retina. (a–c) A single A-type HC was filled with a combination of Lucifer Yellow and Neurobiotin. (a) Shows extensive Lucifer Yellow coupling (green) in this cell type. (b) Shows even greater Neurobiotin coupling (red). (c) Shows the overlay with double-labeled cells fading from yellow to orange because of the wider distribution of Neurobiotin. (d–f) A single B-type HC was filled with the same combination of Lucifer Yellow and Neurobiotin. (d) shows a single B-type HC filled with Lucifer Yellow (green), which indicates that Lucifer Yellow does not pass B-type HC gap junctions. The arrow indicates the axon of the injected cell. (e) Shows extensive Neurobiotin coupling (red) in B-type HCs. (f) Shows the overlay with numerous Neurobiotin coupled B-type HCs in red and a single double-labeled cell in the middle (yellow). From O'Brien, J. *et al*. 2006. Coupling between A-type HCs is mediated by connexin 50 in the rabbit retina. J. Neurosci. 26, 11624–11636.

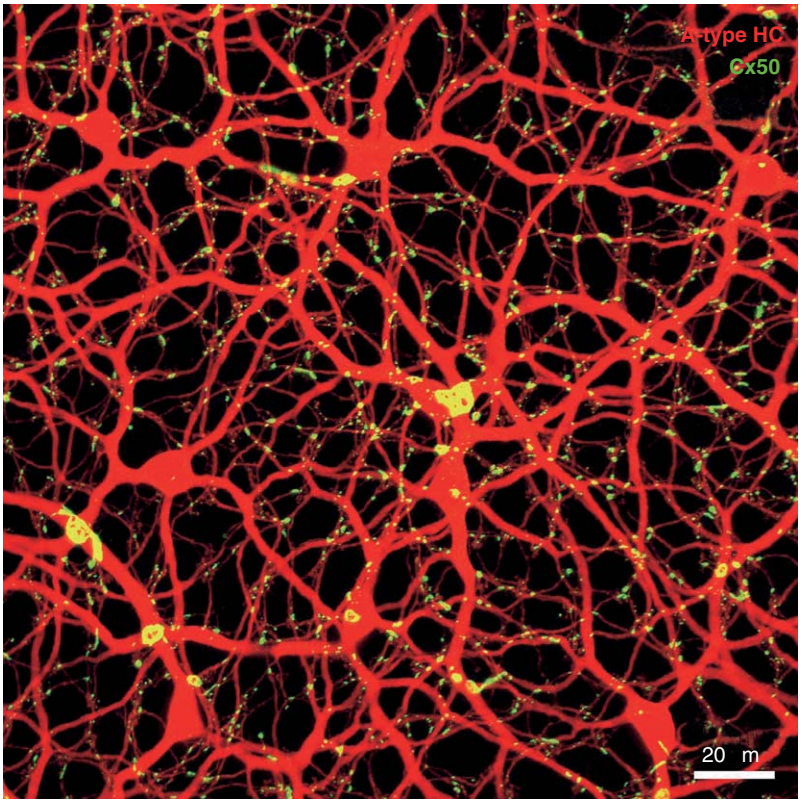

Figure 5 Connexin 50 labeling in the matrix of A-type horizontal cells (HCs) in the rabbit retina. A-type HCs were dye injected with Neurobiotin (red) and the Cx50 staining was coded green, but shows mostly as yellow due to colocalization. Essentially all the Cx50 labeling is on A-type HCs between adjacent or overlapping dendrites. There are numerous small Cx50 plaques among the finer dendrites as well as giant Cx50 plaques between major dendrites. The giant plaque in the center has an area of 63 μm^2 and must contain hundreds of thousands of gap junction channels. Courtesy of Jennifer O'Brien and Stephen C. Massey.

1.23.3.2.2 B-type horizontal cells

B-type HCs are axon-bearing cells in rabbit and cat retina. The somatic end of the cell has many fine, radially symmetrical dendrites, which form a dense meshwork and contact cone pedicles exclusively. The dendrites of B-type somas are also dye coupled, although less so than A-type HCs, since they pass less Neurobiotin and no Lucifer Yellow (Figure 4) (Vaney, D. I., 1993; Mills, S. L. and Massey, S. C., 1994). Presumably, this indicates the presence of different gap junctions in the two types of HC. The passage of Neurobiotin through the gap junctions between the somatic dendrites effectively prevents the diffusion of Neurobiotin along the axon. The tracer would rather spread through the network than pass along the narrow axon. In contrast, if the gap junctions are blocked using a gap junction antagonist such as meclofenamic acid, a complete fill of the axon and the axon terminal (AT) is obtained (Figure 6). Confocal analysis of this material confirms that the AT receives input exclusively from rods (Pan, F. and Massey, S. C., 2007).

The B-type AT is thought to be electrotonically isolated from the somatic dendrites because of the length and fine diameter of the axon, combined with the passive electrical properties of HCs (Nelson, R., 1977). However, evidence from dye injection indicates that the B-type ATs are independently coupled by gap junctions (Vaney, D. I., 1993; Pan, F. and Massey, S. C., 2007). Thus, in the outer retina of the rabbit, there are three independently coupled HC networks. Rats and mice are unusual among mammals in that they have only one type of HC, which is axon bearing and appears to be equivalent to the B-type HC of the rabbit (Peichl, L. and Gonzalez-Soriano, J., 1994).

In the mouse retina, axon-bearing HCs with the morphological appearance of B-type HCs express

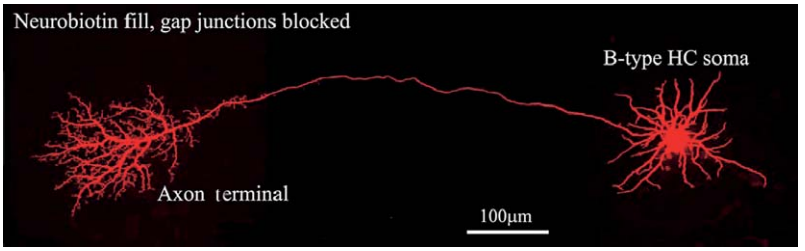

Figure 6 A single B-type horizontal cell (HCs) from the rabbit retina. This cell was filled with Neurobiotin while gap junction coupling was blocked with meclofenamic acid. Because coupling was blocked, the Neurobiotin passed down the axon and filled the axon terminal (AT) structure completely. B-type HCs are axon-bearing cells. The somatic dendrites receive input from cones while the AT structure receives input from approximately 1000 rods. Image courtesy of Feng Pan and Stephen C. Massey.

Cx57, and HC coupling was eliminated in the Cx57 knockout mouse (Peichl, L. and Gonzalez-Soriano, J., 1994; Hombach, S. *et al.*, 2004). This was a convincing demonstration because in the Cx57 knockout mouse, the injected HCs were single fills, including the AT. This results because coupling in the network was eliminated and dye passes along the axon instead of through the network. This is the same effect as when coupling is blocked with a gap junction antagonist (see Figure 6).

1.23.3.2.3 Modulation

Horizontal cell coupling appears to be affected by several neuromodulators including dopamine and nitric oxide (Teranishi, T. *et al.*, 1984; Hampson, E. C. *et al.*, 1994; Xin, D. and Bloomfield, S. A., 1999a; He, S. *et al.*, 2000). The effects of dopamine on goldfish HCs are particularly dramatic but this has been more difficult to demonstrate in the mammalian retina. It may be that there are additional factors to be uncovered in the mammalian retina. By inhibiting gap junction coupling, dopamine reduces the size of the receptive field. In addition, dopamine also increases the amplitude of the response to a small spot because the signals do not spread through the network. This suggests that HC coupling is plastic and that the strength and spatial properties of HC feedback can be modulated by light intensity or circadian processes (Teranishi, T. *et al.*, 1983).

1.23.3.2.4 Horizontal cell feedback

Despite the critical importance of HC feedback to photoreceptors in the outer retina, the exact mechanism by which this occurs remains unsolved. A large and convincing body of work suggests that feedback modulates the calcium current in photoreceptor terminals but the mechanism by which HCs control feedback is unknown (Kamermans, M. and Spekreijse, H., 1999). Classical neurotransmitters do not account for HC feedback and, in the absence of conventional candidates, electrical transmission via hemichannels has been proposed (Kamermans, M. *et al.*, 2001). The idea is that open hemichannels in the tips of HC dendrites pass a current that, in the restricted space of the cone pedicle invagination, can affect voltage-dependent calcium channels in the cone pedicle and thus influence glutamate release. In support of this hypothesis, carbenoxolone, a gap junction antagonist, also reduces HC feedback (Kamermans, M. *et al.*, 2001). However, carbenoxolone has also been shown to block calcium channels and thus may affect glutamate release from cones directly (Vessey, J. P. *et al.*, 2004). An alternative nonconventional mechanism for HC feedback involves the release of protons that may in turn modulate voltage-dependent calcium channels (DeVries, S. H., 2001). In support of this model, additional buffering reduced feedback but the mechanism controlling the release or uptake of protons is unknown (Vessey, J. P. *et al.*, 2005; Cadetti, L. and Thoreson, W. B., 2006). Regardless of which alternative is finally established, it seems likely that HC feedback is mediated by a novel mechanism.

1.23.3.3 AII Amacrine Cells/ON Cone Bipolar Cells, a Complex Heterocellular Network

Cone bipolar cells come in ON and OFF varieties that make direct connections with ganglion cells. In contrast, there is only one type of rod bipolar cell, which is connected to the AII amacrine cell. In turn, the AII splits the signals into ON and OFF pathways by connecting to OFF bipolar cells via glycinergic synapses and to ON bipolar cells via gap junctions. It is often said that the rod signals piggyback on the cone pathways. The heterocellular gap junctions with

ON bipolar cells are the conduits for the transfer of rod signals into the ON cone pathways (Strettoi, E. *et al.*, 1992; Strettoi, E. *et al.*, 1994; Bloomfield, S. A. and Dacheux, R. F., 2001).

The AII amacrine cell is the most numerous amacrine cell type in the mammalian retina. They are well coupled by prominent gap junctions that were described in the first morphological reports of AII amacrine cells (Famiglietti, E. V. and Kolb, H., 1975). The extent of coupling was dramatically confirmed by Neurobiotin injections, which yield a mosaic of AII amacrine cells and a large population of overlying ON cone bipolar cells (Figure 7) (Hampson, E. C. *et al.*, 1992; Mills, S. L. and Massey, S. C., 1995). The AIIs are all located in the amacrine cell layer, adjacent to the inner plexiform layer (IPL), while the bipolar cells have somas toward the top of the inner nuclear layer. The dye-coupled ON cone bipolar cells are made up from four to five morphological types so this is truly a complex heterocellular network (McGuire, B. A. *et al.*, 1984).

AII amacrine cells have a stout primary dendrite that tapers into the IPL. The top sublayer of the IPL contains a dense meshwork of dopaminergic dendrites, which are penetrated by the AII processes. When viewed in wholemount, it looks like there are holes in the dopaminergic plexus and each one contains an AII amacrine cell. The dopaminergic dendrites form a ring of varicosities around every AII amacrine cell. This is the motif of a major synaptic input and dopamine dramatically modulates coupling in the AII network via PKA (Hampson, E. C. *et al.*, 1992; Mills, S. L. and Massey, S. C., 1995). AII gap junctions are also modulated by light, with reduced coupling in dark or bright conditions and most coupling at intermediate light intensity (Bloomfield, S. A. and Volgyi, B., 2004). The exact details between dopamine levels, receptor subtypes, light modulation, circadian mechanisms, and other potential modulators have not yet been worked out. However, the input of dopamine, the dominant signal for light adaptation, to the AII network, a major intersection of rod and cone pathways, has clear functional significance.

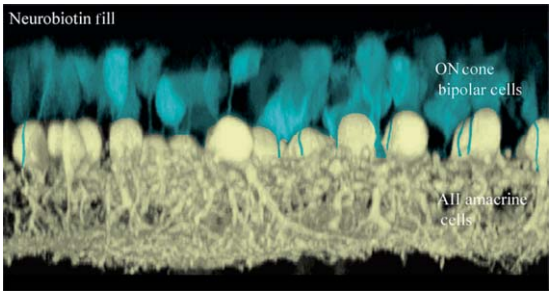

Figure 7 Three-dimensional reconstruction from a confocal series to show the heterocellular network of AII amacrine cells and ON cone bipolar cells in the rabbit retina. A single AII amacrine cell was filled with Neurobiotin. AII amacrine cells (beige) lie adjacent to the inner plexiform layer (IPL) and overlap extensively. ON cone bipolar cells (three to five types, blue) have cell bodies higher in the inner nuclear layer (INL) and they produce descending axons that are lost in the matrix of AII dendrites. Image courtesy of Brady Trexler and Stephen C. Massey.

It is well established that AII amacrine cells are coupled by Cx36 gap junctions (Feigenspan, A. *et al.*, 2001; Mills, S. L. *et al.*, 2001). Cx36 is predominantly expressed by AII amacrine cells and it occurs at dendritic crossings in the AII matrix. The Cx36 staining is punctate and we have learned that this type of labeling pattern is diagnostic for gap junction proteins. This indicates that AII/AII gap junctions are composed of homotypic, Cx36/Cx36 gap junctions. The level of Cx36 expression in AII amacrine cells is astonishing; the density is high and the Cx36 plaques are larger than other gap junctions in the IPL. So far, there have been few good examples to compare with. Now, as we start to uncover new coupling patterns, we find that the expression of connexins in other amacrine cell types is relatively meager. By comparison, the AII matrix has a heavy concentration of Cx36 gap junctions. This is suggestive of a special role for the AII network, which is unusually well coupled in all mammalian retinas.

1.23.3.3.1 AII/ON cone bipolar gap junctions

In addition to AII/AII gap junctions, Cx36 immunoreactivity occurs at AII/ON cone bipolar contacts (Figure 8). However, the AII/bipolar gap junctions have different properties than the AII/AII junctions. In early morphological work, it was noticed that the AII/bipolar gap junctions have an asymmetrical appearance (Strettoi, E. *et al.*, 1992; Wassle, H. *et al.*, 1995). Dye coupling studies with a series of biotinylated tracers related to Neurobiotin, show that the AII/bipolar gap junctions tend to exclude the high molecular weight compounds (Mills, S. L. and Massey, S. C., 1995; 2000). All else being equal, the size exclusion probably indicates that the AII/bipolar gap junction has a smaller unitary conductance than the AII/AII gap junctions. Furthermore, the two gap junction types have different pharmacological properties. The AII/AII gap junctions are preferentially closed by dopamine and cAMP analogs while the

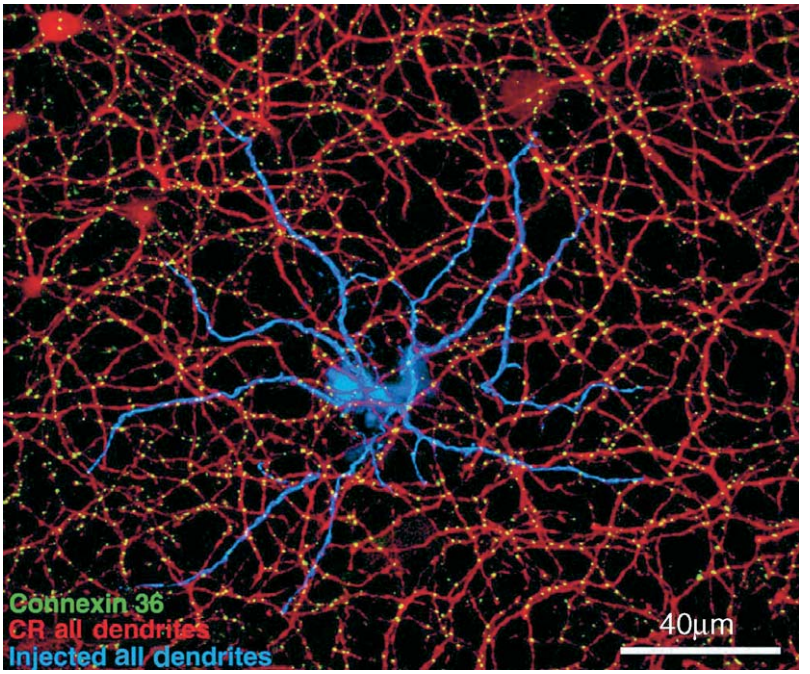

Figure 8 AII/AII gap junctions are Cx36/Cx36 in the rabbit retina. The fine dendrites of a single dye injected AII amacrine cell are shown in blue. The mosaic of surrounding AII amacrine cells was stained with an antibody against calretinin (red). Cx36 labeling is shown in green but appears mostly yellow due to colocalization with the AII matrix. Essentially, all the Cx36 plaques occur in the AII matrix, mostly at dendritic crossings. This is especially obvious where blue dendrites from the single dye injected AII cross red dendrites from neighboring AII amacrine cells. Image analysis shows there is a high probability of a Cx36 gap junction where AII dendrites cross. From Mills S. L. *et al*. 2001. Rod pathways in the mammalian retina use connexin36. J. Comp. Neurol. 436, 336–350, 2001.

AII/bipolar gap junctions respond better to NO donors and cGMP analogs (Mills, S. L. and Massey, S. C., 1995; Xin, D. and Bloomfield, S. A., 1999b). One explanation could be that the AII/bipolar gap junctions are heterotypic, with Cx36 on the AII side and a different connexin expressed in bipolar cells. This would be a heterotypic gap junction.

AII amacrine cells are glycinergic inhibitory interneurons and they express a glycine transporter. In contrast, bipolar cells are excitatory and use glutamate as a neurotransmitter. However, ON cone bipolar cells also contain substantial levels of glycine despite the fact that they do not express a glycine transporter (Cohen, E. and Sterling, P., 1986). The source of the glycine in bipolar cells is via the gap junction with AII amacrine cells. This was established by showing that the distribution of glycine can be changed by blocking gap junctions with carbenoxolone (Vaney, D. I. *et al*., 1998). In the presence of carbenoxolone, ON cone bipolar cells no longer accumulate glycine via the gap junctions with AII amacrine cells. In transgenic mice that express a Cx45 reporter, many amacrine cells and bipolar cells are labeled. Furthermore, in the Cx45 knockout, the labeling pattern for glycine was changed such that bipolar cells no longer contained glycine (Maxeiner, S. *et al*., 2005). In other words, in the Cx45 knockout, the gap junctions between bipolar cells and AII amacrine cells were blocked or absent. This strongly suggested that Cx45 plays a role at AII/bipolar gap junctions. Subsequently, double labeling with Cx36 and Cx45 showed the presence of punctate pairs with adjacent Cx36/Cx45 labeling and these structures were located at AII/bipolar cell contacts (Han, Y. and Massey, S. C., 2005; Dedek, K. *et al*., 2006). In summary, these results indicate that AII/bipolar cell gap junctions are heterotypic with Cx36/Cx45 gap junctions. There may be some variability among the bipolar cells because at least one specific bipolar subtype in the mouse retina expresses Cx36 (Han, Y. and Massey, S. C., 2005; Lin, B. *et al*., 2005).

1.23.3.3.2 Physiology

Paired recordings indicate that AII/AII gap junctions are bidirectional with a conductance in the range of 700 pS (Veruki, M. L. and Hartveit, E., 2002a). AII

amacrine cells are noisy neurons with a lot of spontaneous activity. This might be expected for a system that sits close to threshold so as to impart maximum sensitivity in low light conditions. Importantly, the gap junctions can synchronize action potentials between adjacent AII amacrine cells (Veruki, M. L. and Hartveit, E., 2002a; 2002b). This is consistent with the idea that gap junctions in the AII network serve the purpose of signal averaging and noise reduction in the high-gain rod bipolar pathway (Smith, R. G. and Vardi, N., 1995; Vardi N., and Smith, R. G., 1996).

Paired recordings also show that AII/bipolar gap junctions are bidirectional (Veruki, M. L. and Hartveit, E., 2002a). Under the right circumstances, Neurobiotin can also pass from AII amacrine cells to bipolar cells (Trexler, E. B. *et al.*, 2001; Veruki, M. L. and Hartveit, E., 2002b) and, of course, this is also the route for glycine (Vaney, D. I. *et al.*, 1998). This implies that electrical signals can pass, not only from the AII into bipolar cells but also from the cone pathways into the AII. When the rod bipolar input to the AII was blocked with a glutamate antagonist, there was a remaining light-driven signal with the characteristics of electrical input via the gap junctions with bipolar cells (Trexler, E. B. *et al.*, 2005). The idea of dual inputs to AII amacrine cells, via a chemical synapses with rod bipolar cells, and electrical synapses from ON cone bipolar cells was confirmed in experiments with transgenic mice. In the absence of rod bipolar inputs, the electrical input remained but it was eliminated in Cx36 knockout mice (Pang, J. J. *et al.*, 2007). Thus, AII amacrine cells may play a dual role in retinal circuitry: in dim light, they average rod bipolar signals for distribution to both ON and OFF cone bipolar cells while in bright conditions, input via gap junctions with ON bipolar cells may provide crossover inhibition to OFF cone bipolar cells.

Finally, in an elegant and important series of experiments, the Bloomfield lab has explored the physiological consequences of eliminating Cx36 gap junctions in a line of transgenic mice (Deans, M. R. *et al.*, 2002). In the wild-type mouse, ganglion cells show a variety of intensity response curves. This includes some ganglion cells that only respond at intensities above cone threshold. This implies that they receive input from an ON cone bipolar subtype that receives no rod input and is therefore not coupled to the AII network. However, in the Cx36 knockout there are significant changes. In particular, there is no rod-driven input to ON ganglion cells. At threshold intensities, rod signals pass through the high-gain rod bipolar pathway and through the AII/bipolar gap junctions and so to ON ganglion cells. But, in the Cx36 knockout, AII/AII and AII/ON bipolar coupling are eliminated. At intermediate intensities, the pathway is thought to pass via rod/cone coupling into the cone pathways. Rod/cone gap junctions depend on Cx36 expression in cones and are also eliminated in the Cx36 knockout. These experiments indicate that Cx36 is essential for processing rod-driven ON signals (Deans, M. R. *et al.*, 2002). This is the first time that a requirement for an electrical synapse has been demonstrated in a specific neuronal circuit in the mammalian CNS. The changes to OFF ganglion cell responses are more subtle. Rod-driven signals are still present in OFF pathways because there is no gap junction along this pathway. However, the sensitivity of rod-driven signals was reduced by a log unit, perhaps due to the absence of AII/AII coupling in the Cx36 knockout (Volgyi, B. *et al.*, 2004). This result is consistent with the idea that averaging in the AII network is necessary to provide maximum sensitivity in retinal circuits (Bloomfield, S. A. and Volgyi, B., 2004).

1.23.3.4 Ganglion Cells

Many ganglion cell types are also coupled. At first, this seems counterintuitive because coupling between adjacent cells of the same type would seem to spread the signals leading to a loss of spatial resolution. However, across many mammalian species including cat, rabbit, rodent, and primate, Neurobiotin injections reveal ganglion cell to ganglion cell coupling as well as coupling to one or more amacrine types. For example, in the rabbit, OFF α ganglion cells are coupled to surrounding OFF α ganglion cells and as many as a hundred amacrine cells (Hu, E. H. and Bloomfield, S. A., 2003). Of course, the cells are only visible after the Neurobiotin has been developed and often the dye-coupled cells are faintly labeled compared to the injected cell. Frequently, the coupled cells are wide-field amacrine cells but a complete description has not been possible in most cases. In a different approach, the use of a novel fluorescent nuclear tracer, Po-pro-1, which is gap junction permeable, has been used to make the somas of the coupled cells visible so they can be individually targeted (Hoshi, H. *et al.*, 2006). This method has confirmed that many of the coupled amacrine cells are wide-field axon-bearing types.

1.23.3.4.1 Alpha ganglion cells

α Ganglion cells are dye coupled but there is some variation across species. In the rodent retina, both

subtypes are coupled but in the rabbit retina only OFF α ganglion cells are coupled. This provides a useful test case to compare the effects of cell coupling: the spikes of ON α ganglion cells are not correlated whereas the spikes between neighboring OFF α ganglion cells are synchronized (DeVries, S. H., 1999; Hu, E. H. and Bloomfield, S. A., 2003). This indicates that electrical coupling via gap junctions underlies the correlated spikes in neighboring OFF α ganglion cells. In the rat retina, bidirectional electrical coupling between α ganglion cells resulted in precisely synchronized firing after current injection and electron microscopy revealed dendrodendritic Cx36 gap junctions at contact points between dye-coupled α ganglion cells (Hidaka, S. *et al.*, 2004). Most investigators have reported Cx36 at dendritic crossings between α ganglion cells but there is residual dye coupling between OFF α cells in the retina of the Cx36 knockout mouse (Schubert, T. *et al.*, 2005a; Volgyi, B. *et al.*, 2005). At least some of the ganglion cell to amacrine cell coupling is also Cx36 but other connexins are probably used at a subset of gap junctions. In the mouse retina, bistratified ganglion cells may be connected via Cx45 gap junctions because coupling is absent in the Cx45 knockout (Schubert, T. *et al.*, 2005b).

The common occurrence of electrical coupling among ganglion cell types has been independently confirmed by examining their biochemical signatures. Gap junctions with amacrine cells are thought to provide a route for metabolic coupling so that certain ganglion cells contain amacrine cell neurotransmitters such as GABA or glycine (Marc, R. E. and Jones, B. W., 2002). In addition, recording from the rabbit retina with a multielectrode array shows that 5/11 physiologically classified ganglion cells are coupled (DeVries, S. H., 1999). There is consistency between these different approaches such that OFF α ganglion cells in the rabbit retina are dye coupled, have synchronized firing, and contain GABA while ON α ganglion cells do not.

1.23.3.4.2 ON/OFF directionally selective ganglion cells

In the adult rabbit retina, there are four subtypes of ON/OFF directionally selective (ON/OFF DS) ganglion cells with orthogonal preferred stimulus directions. A subset of the ON/OFF DS ganglion cells, presumably responding to one of the four preferred axes, is dye coupled. These cells form a tiling pattern with a coverage factor close to one (Vaney, D. I., 1994). In contrast, other ON/OFF DS cells, presumably with different axes, overlie the coupled subtypes and their dendrites cofasciculate. The function of coupling in the ON/OFF DS cells is unknown but it may be related to development because coupling among all ON/OFF DS subtypes is much more prevalent in the neonatal retina (DeBoer, D. J. and Vaney, D. I., 2005).

1.23.3.4.3 Synchronized firing

Correlated firing patterns have been recorded between many ganglion cell types using a multielectrode array and it has been suggested that synchronized spikes could transmit additional information as a multineuronal code (Meister, M., 1996). Pairwise and adjacent interactions between primate parasol ganglion cells, most likely due to gap junction coupling, accounted for nearly all multineuronal firing patterns (Shlens, J. *et al.*, 2006). An alternative explanation is that synchronized firing delivers closely timed spikes to the lateral geniculate nuclei (LGN), which have a much higher probability of eliciting a postsynaptic spike (Usrey, W. M. *et al.*, 1998). Adjacent ON DS ganglion cells in the rabbit retina are dye coupled to many amacrine cells (Figure 9) and they also produced synchronous firing

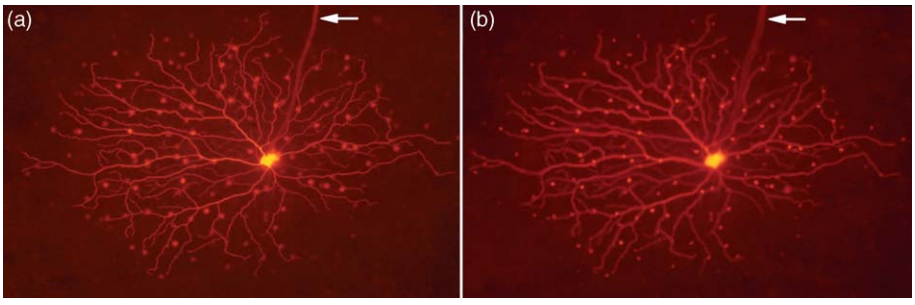

Figure 9 Dye coupling between amacrine cells and an ON directionally selective (ON DS) ganglion cell in the rabbit retina. A single ganglion cell with the morphology of an ON DS ganglion cell was filled with Neurobiotin. (a) Focus on the ON DS ganglion cell dendrites. (b) Focus on the cell bodies of numerous dye-coupled amacrine cells. Image courtesy of Stephen C. Massey.

patterns (Ackert, J. M. *et al*., 2006). These cells project to the accessory optic system and may play a role in image tracking or stabilizing the retinal image. The correlated firing of ON DS ganglion cells was also dependent on the direction of the stimulus: null axis stimuli generated fewer spikes that were not synchronized. This suggests that preferred axis motion not only generates more spikes but those from neighboring cells are also synchronized and thus much more likely to produce a postsynaptic response (Ackert, J. M. *et al*., 2006). This is in effect another form of signal averaging and noise reduction such that asynchronous signals are selectively filtered.

1.23.4 Conclusion

Gap junctions are common circuit elements in the mammalian retina and four different neuronal connexins have been identified. As in other regions of the CNS, Cx36 is the dominant connexin, serving AII coupling and photoreceptor coupling. Cx45 coupling is also found in certain amacrine and ganglion cells and heterotypic Cx36/Cx45 gap junctions are found between AII amacrine cells and cone bipolar cells. Cx50 and/or Cx57 appear to be responsible for HC coupling in the retina. There may be additional gap junction proteins still to be identified. Clear functional roles have been assigned to different gap junctions in stereotyped neuronal circuits. It seems that the signal averaging properties of gap junctions serve a vital noise reduction strategy in the early steps of vision. The modulation of gap junctions may also contribute to retinal plasticity. This is important because the retina is a self-adjusting neuronal network that continuously adapts to the visual input. Optimizing retinal function over a wide variety of conditions must have been associated with a high survival value over evolutionary time.

Glossary

plasticity State of being able to be reformed or refined. In the nervous system, plasticity refers to the modifiability of neuronal synaptic circuits. Plasticity is expressed as morphological and/or functional changes.

developmental plasticity Capability of neuronal circuits to be modified during initial maturation.

adaptive plasticity Ability of matured neuronal circuits to change functional status in response to alterations of environmental conditions.

compensatory plasticity Ability of neuronal circuits to make compensatory changes in structure or function in responding to pathological conditions and aging.

visual deprivation Conditions for animals in which normal visual stimuli are degraded or absent. These conditions could include lack of any light or selective absence of form, contrast or color.

dark rearing Conditions in which animals are housed in total darkness.

light adaptation Processes by which the visual system adjusts itself to increased ambient light. These processes include a reduced sensitivity of phototransduction in rods and cones, loss of functional photopigments in rods and cones (for very bright lights), changes in the gain of synaptic signal transfer and pupil constriction.

dark adaptation The process by which the visual system adjusts itself to decreased ambient lighting conditions. It is determined by the percentage of molecules of the rod photopigment, rhodopsin, that are bleached. Rhodopsin regenerates with a slow time course so that one would need 30–45 min to regenerate all bleached rhodopsin and regain sensitivity to dim light from a light adapted status.

RGC receptive field The area of visual field or retina over which an RGC can be activated, directly or indirectly.

RGC dendritic field The dendritic processes of RGCs extend laterally across the retina. The dendritic field is the physical area of retina encompassed by the usually circularly shaped 'tree' of all dendritic branches.

parallel synaptic pathway This term refers to specific synaptic structures carrying different aspects of neuronal perception in the nervous system. Many visual signals are processed by parallel synaptic pathways in visual system. For example, there are cells that respond to objects brighter than the background (increment of brightness or ON response) and the cells that respond to the objects darker than the background (decrement of brightness or OFF response), among bipolar and ganglion cells in the retina, cells in the lateral geniculate nucleus and visual cortex. These two types of visual signal are separated from each other after they are generated at the first synapses in the retina and do not come together again until the visual cortex is reached. Thus, there are clearly separated neuronal structures to process the two types of signal and little interaction between them along the way.

ionotropic glutamate receptor A class of membrane receptors that is activated by the neurotransmitter glutamate and are comprised of subunits that change their molecular configuration to allow charged ions to flow directly across cell walls. These are fast acting receptors that can be divided structurally and pharmacologically into three different classes: AMPA, Kainate, and NMDA receptors.

metabotropic glutamate receptor A class of membrane receptors that are activated by glutamate and are coupled to intracellular second messenger cascades. Glutamate binding to metabotropic receptors triggers this cascade. Glutamate binding to the mGluR6 metabotropic receptors of retinal ON bipolar cells results in the closure of cationic channels in the membrane with concomitant hyperpolarization.

bi-laminated RGC Retinal ganglion cell with dendritic processes that arborize in both sublaminae of the inner plexiform layer. The ganglion cells can receive synaptic inputs from both ON and OFF bipolar cells.

mono-laminated RGC Retinal ganglion cells with dendritic processes that arborize exclusively in one sublamina of the inner plexiform layer.

Plasticity in sensory, integrative, and motor pathways in the central nervous system (CNS) enables organisms to adapt to the environment and optimize performance under various physiological and pathological conditions. Although, neuronal circuits are for the most part hard wired, connectivity between neurons, synaptic structures and their basic behavior, and neuronal processing can be modified and refined. Plasticity is a commonly used term to denote the capability of neuronal systems, small circuits, and single cells to refine and modify their structure and behavior in response to environmental stimuli. In the visual system reorganization and refinement of neuronal pathways can take place during development or in mature animals including humans. The reorganization of the eye-specific ocular dominance columns in visual cortex in response to visual deprivation of one eye is a now classic example of plasticity during postnatal maturation. The adjustment of the gain of vestibular

ocular reflex (VOR) in response to new glasses is an example of plasticity in adults (Boyden, E. S. *et al.*, 2004).

Much of what we have learned about plasticity of synaptic wiring in sensory systems has been derived from studies in which functional and morphological changes have been documented in higher sensory centers of the brain. Little attention has been paid to plastic changes in retinal circuitry. It was commonly assumed previously that retinal synaptic circuitry matures early in development. Indeed, many aspects of synaptic signaling in retina reach maturity before the retina receive visual stimulation. Most of the morphological features of the retina and the expression of synthesizing enzymes, transporters, and receptors for neurotransmitters of retinal neurons resemble those in adult animals by the time of eye opening in mice, rats, rabbits, cats, and ferrets (Fisher, L. J., 1979; Greiner, J. V. and Weidman, T. A., 1981; Redburn, D. A. and Madtes, P., 1987; Pow, D. V. and Barnett, N. L., 2000; Sassoe-Pognetto, M. and Wässle, H., 1997; Johnson, J. *et al.*, 2003). Functionally, early experiments using rabbit retina showed that the size of retinal ganglion cell (RGC) receptive fields, RGC directional selectivity and light-evoked eye movements reached mature levels early during postnatal development (Daw, N. W. and Wyatt, H. J., 1974; Masland, R. H., 1977). However, recent and not so recent, studies have established that retinal circuitry is functionally and structurally malleable during postnatal development.

In this chapter we will discuss three types of plasticity in retinal circuitry. Our focus is on structural and functional modification of circuitry postsynaptic to rods and cones. Plasticity inherent in the structure and visual signaling of rods and cones has been well documented elsewhere (Dearry, A. and Burnside, B., 1986; Lamb, T. D. and Pugh, E. N., Jr., 2004). In the first two sections we will concentrate on changes in retinal circuitry induced by light itself. These will include alterations induced by visual deprivation during early postnatal maturation and short term changes in functional connectivity and activity of retinal circuitry evoked by background lighting conditions in adult retina, commonly termed light and dark adaptation. Finally, we will discuss alterations in synaptic morphology in retinas in which rods and cones degenerate or lose their visual signaling capabilities or in retinas in which genetic mutations lead to deficits in synaptic function.

1.24.1 Visual Activity Regulates Synaptic Wiring in Developing Retina

1.24.1.1 Visual Deprivation During Postnatal Development Modifies Dendritic Arborization Patterns and Visual Responses of Retinal Ganglion Cells

1.24.1.1.1 Dark rearing expands retinal ganglion cells receptive fields and dendritic coverage in turtle retina

A cogent example of how light deprivation can influence the receptive field sizes and structure of dendritic fields during early development was reported in turtle retina. Electrophysiologically recorded RGC receptive fields in dark-reared posthatched turtles can expand to twice the size of RGC receptive fields of adults raised in cyclic light (Sernagor, E. and Grzywacz, N. M., 1996). Analysis of dye-filled RGC dendritic arbors showed that dark rearing produced excessive growth of dendrites in the large-field RGCs of turtle, consistent with the larger receptive fields recorded in response to light patterns (Mehta, V. and Sernagor, E., 2006). While the effects of visual deprivation on RGC dendritic field coverage has not been reported in mammalian retina, during postnatal development visual inputs do regulate the laminar patterns of RGC dendritic arbors in the inner plexiform layer (IPL), and hence the relative proportions of exclusive inputs from the ON and OFF pathways.

1.24.1.1.2 Dark rearing retards developmental segregation of ON and OFF pathways in retinal ganglion cells

Separate parallel retinal synaptic pathways transmit signals about light increments (ON) and light decrements (OFF). The separation of ON and OFF pathways originates at the first synapse of the retina between photoreceptors and bipolar cells (Figure 1). In all vertebrate retinas, light stimulation hyperpolarizes the membrane potentials of photoreceptors (rods and cones) and decreases the synaptic release of glutamate from these cells. Glutamate released from photoreceptors activates ionotropic glutamate receptors on cone-driven OFF bipolar cells and depolarizes their membrane potentials. Glutamate activates a metabotropic glutamate receptors on the cone-driven ON bipolar cells and all rod-driven bipolar cells and thereby hyperpolarizes the membrane potentials of these cells (see Chapters Mammalian Rod Pathways and Contributions of Bipolar Cells to Ganglion Cell Receptive Fields for details). This sign

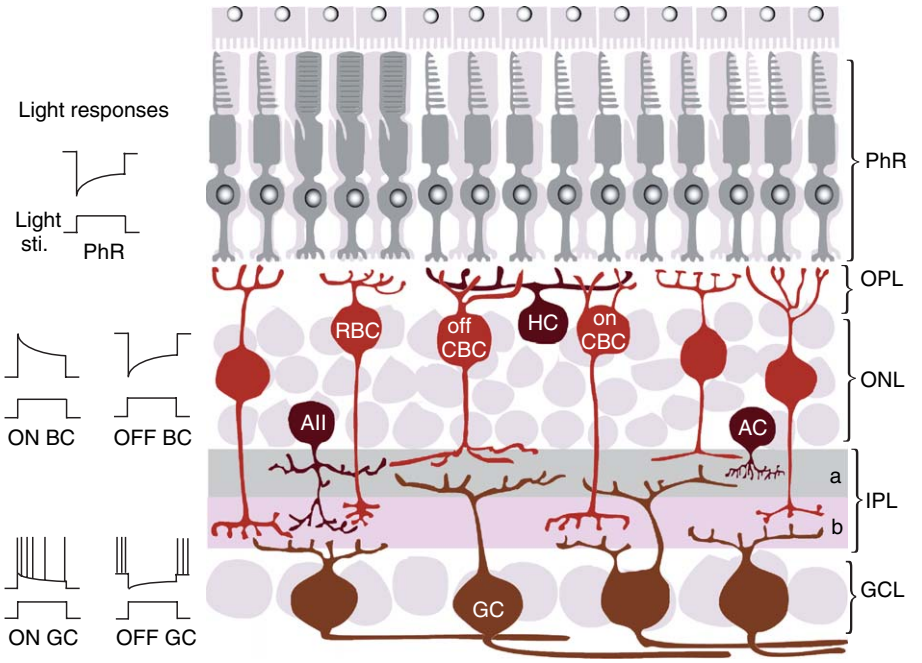

Figure 1 A schematic drawing of the principal anatomical components, synaptic connections, and representative light responses of ON–OFF pathways of mammalian retina. Photoreceptors (rods and cones) synapse with bipolar and horizontal cells (HCs) in the outer plexiform layer (OPL). ON and OFF signals are generated in the OPL by the activation of metabotropic and ionotropic glutamate receptors on the ON and OFF bipolar cells, respectively. All ON bipolar cell synapse with retinal ganglion cells (RGCs) in sublamina *b* and all OFF bipolar cell make synapses with RGCs in the sublamina *a* of inner plexiform layer (IPL). A subpopulation of RGCs receives synaptic inputs from both ON and OFF bipolar cells. Bipolar cells that receive rod inputs synapse with AII amacrine cells, which in turn make electrical synapse with cone-driven OFF bipolar cells and chemical synapse with cone-driven ON bipolar cells. Light responses in outer retinal neurons, such as photoreceptors, bipolar cells, and HCs, are graded potentials. In the inner retina RGCs and amacrine cells (ACs) typically signal more transient depolarization and action potentials. PhR, photoreceptor; GC, ganglion cell; OFF CBC, cone-driven OFF bipolar cell; ON CBC, cone-driven ON bipolar cell; RBC, rod-driven bipolar cell. Adapted from Xu, H. P. and Tian, N. 2004. Pathway-specific maturation, visual deprivation, and development of retinal pathway. Neuroscientist 10, 337–346, with permission from SAGE Publications Inc.

reversing and sign conserving action of glutamate on the ON and OFF bipolar cells, respectively, separates the increment and decrement luminance signals into ON and OFF pathways. At the level of synaptic inputs to RGCs the separation of ON and OFF pathways is preserved by the selectivity of the synaptic connections between bipolar and RGCs in distinct layers of the IPL. Despite the enormous diversity of the structural and functional properties among different subtypes of RGCs, all ON RGC dendrites ramify only in the sublamina *b* of the IPL and synapse with ON bipolar cells. In contrast, all OFF RGC dendrites ramify only in the sublamina *a* of the IPL and synapse with OFF bipolar cells (Famiglietti, E. V. and Kolb, H., 1976; Nelson, R. *et al.*, 1978). A subset of RGCs, the ON–OFF RGCs, ramify their dendrites in both sublaminas and signal both the onset and termination of light (Amthor, F. R. *et al.*, 1984). Thus, the ON and OFF pathways are maintained functionally and structurally separated.

Early in postnatal development, the dendrites of a large percentage of RGCs ramify diffusely throughout the IPL (Maslim, J. and Stone, J., 1988; Bodnarenko, S. R. *et al.*, 1995; 1999; Wang, G. Y. *et al.*, 2001; Diao, L. *et al.* 2004). With subsequent maturation, RGC dendrites are seen to be much more monostratified with most or all of the arbors restricted to sublamina *a* or *b*. This laminar refinement predicts there is an age-dependent decrease in the number of RGCs receiving synaptic inputs from both ON and OFF bipolar cells. Indeed, analysis of RGC dendritic arborization in mouse retina shows that whereas 53% of RGCs in postnatal (P)10-aged animals ramify in both sublamina *a* and *b* of IPL only 29% of mouse RGCs in P30-aged animals ramify in both sublaminas *a* and *b* (Tian, N. and Copenhagen, D. R., 2003). This developmental

pruning of RGC dendrites is one of the best examples of the maturational reorganization of neuronal synaptic circuitry (Wong, R. O. L. and Ghosh, A., 2002) and has been found in cats (Dann, J. F. *et al.*, 1988; Maslim, J. and Stone, J., 1988; Bodnarenko, S. R. *et al.*, 1995), ferrets (Bodnarenko, S. R. *et al.*, 1999), rabbits (Wong, R. O. L., 1990), rats (Yamasaki, E. N. and Ramoa, A. S., 1993), and mice (Bansal, A. *et al.*, 2000; Diao, L. *et al.*, 2004).

As a technical note, it should be mentioned that the morphological characterization of RGC dendritic patterns have been facilitated significantly by the availability of mouse lines in which green fluorscent protein (GFP) or yellow fluorscent protein (YFP) is driven by the Thy1 promoter (Feng, G. *et al.*, 2000). In line H of the Thy1-YFP-expressing mice, numerous YFP labeled RGCs are randomly distributed throughout the retina (Figure 2). Confocal microscopy of these individual cells in whole mounted retinas has allowed experimenters to classify the arborization patterns of the RGCs (Tian, N. and Copenhagen, D. R., 2003; Coombs, J. *et al.*, 2006). Figure 3 shows an example of two RGCs obtained from a Thy1-YFP retina. The inset shows the color coding scheme by which processes in sublamina *a* are colored green and processes in sublamina *b* and the ganglion cell layer are colored blue.

The developmental refinement of RGC dendritic arbors discussed above is reflected physiologically as an age-dependent decrease in the number of RGCs that respond with spikes at the onset and termination of a light. This maturational decline in the percentages of ON–OFF RGCs has been observed electrophysiologically in mouse, cat, and ferret retinas (Bisti, S. *et al.*, 1998; Wang, G. Y. *et al.*, 2001; Tian, N. and Copenhagen, D. R., 2003). These results serve to illuminate the observation that, because the ON and OFF sublaminas of the IPL are so well regulated, the retina proves to be one of the best places in the nervous system to directly link structural characteristics with functional responsiveness at the cellular level.

The activity-dependent developmental plasticity of mammalian retina is shown by the finding that light deprivation retards the maturational conversion of bilaminated RGC dendrites into monolaminated structures, and the consequent decline in the percentage of ON–OFF RGCs (Tian, N. and Copenhagen, D. R., 2003). Tian N. and Copenhagen D. R. (2003) compared the lamination patterns of RGCs in cyclic-reared mice to those in dark-reared mice. At P30, $53\% \pm 2.5\%$ of the RGCs were classified as bilaminated in the dark-reared mice versus $29\% \pm 3\%$ in cyclic light-reared mice. This difference was highly significant. The percentage of bilaminated cells in the P30 dark-reared animals was very close to the P10-aged mice raised in cyclic light ($53\% \pm 2.5\%$ vs. $53\% \pm 2.7\%$). These anatomical findings predicted that many more RGCs in the P30 dark-reared animals should be ON–OFF responsive RGCs. Multielectrode array recordings of light responses from RGCs verified this prediction. In the P27–30-aged mice raised in constant darkness, the percentage of ON–OFF RGCs was more than fourfold higher than age-matched cyclic light-reared mice. Moreover, the percentage of ON–OFF RGCs in the dark-reared mice at P27-30 was comparable to the

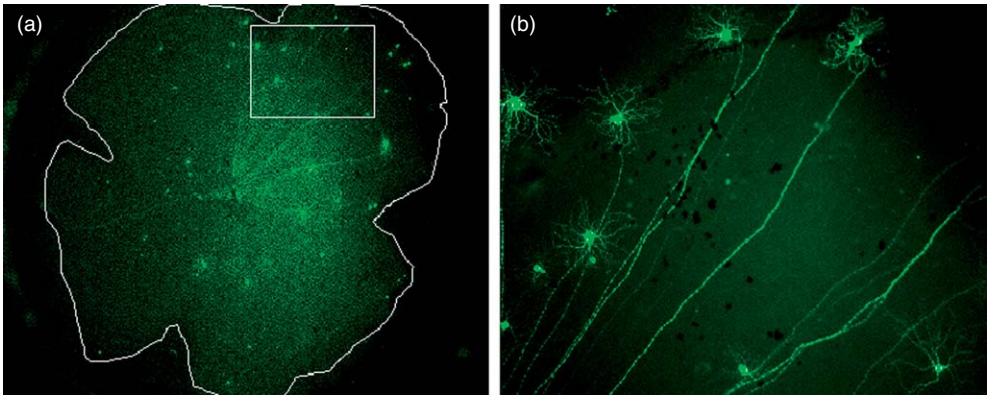

Figure 2 A small percentage of retinal ganglion cells (RGCs) are randomly labeled by YFP expression driven by Thy1 promoter in the H line of Thy1-YFP transgenic mouse. (a) A low magnified view from vitreal side of a flat-mounted retina harvested from a postnatal 30-aged Thy1-YFP-expressing mouse. (b) An enlarged view of the area indicated by the box in panel (a). Somata and dendrites are readily identifiable and the axons from individual RGCs cross the retina from each somata to the optic nerve head. Adapted from Tian, N. and Copenhagen, D. R. 2003. Visual stimulation is required for refinement of ON and OFF pathways in postnatal retina. Neuron 39, 85–96, with permission from Elsevier.

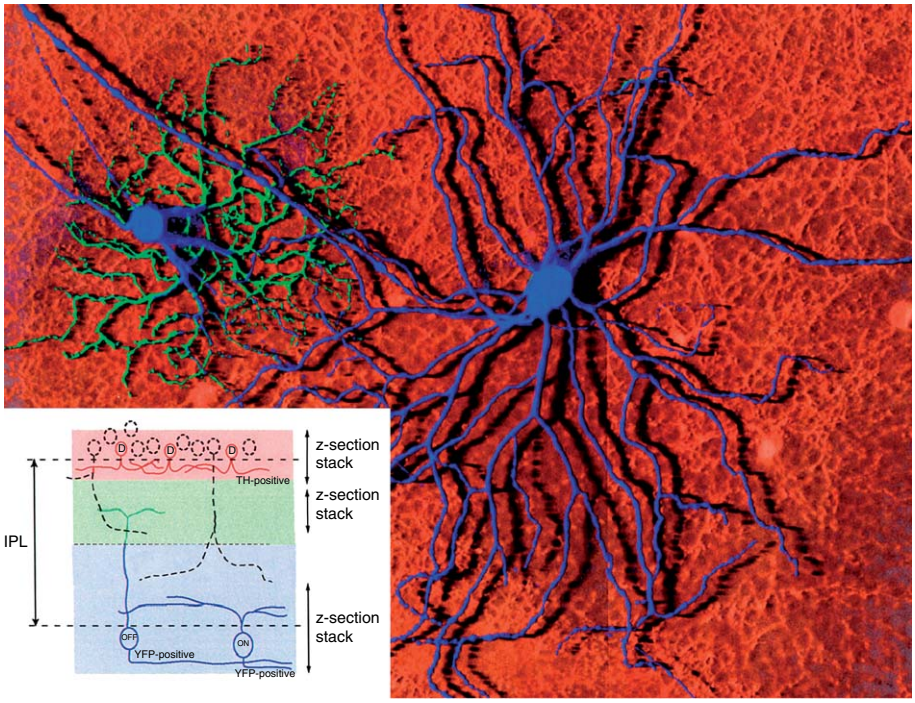

Figure 3 Dendritic ramification patterns of YFP-expression retinal ganglion cells (RGCs) in the inner plexiform layer (IPL) can be determined using confocal microscopy. Stacked image of two YFP-expressing RGCs from a postnatal 30-aged mouse retina. Red label denotes the immunolabeling pattern of TH-positive cells. These dopaminergic cells have their somata positioned at the inner nuclear layer (INL)/IPL border and their processes localized along the INL border of the IPL. TH-positive staining was used here as a marker for the distal edge of the IPL. The green processes show stacked images of YFP-expressing processes obtained from sequential z scans between the IPL/INL border to the middle of the IPL (see inset). The blue processes and somata show stacked images of YFP-expressing RGCs obtained from z scans from the middle of the IPL to the vitreal/RGC border. The OFF RGC is shown with monostratified dendrites (green) in sublamina *a* and a somata and axon (blue) in the proximal retina. The ON RGC has dendrites (blue) restricted exclusively to sublamina *b*.

percentage of ON–OFF RGCs at P10–12. These findings, which have been subsequently confirmed (Landi, S. *et al.*, 2007; Liu, X. *et al.*, 2007; Xu, H. P. and Tian, N., 2007) established that functionally and morphologically, retinal circuits are not hard-wired at birth and that the development of retinal wiring is influenced by visual inputs to the eye.

1.24.1.1.3 Molecular or genetic mechanisms mediating this activity-dependent developmental plasticity remain elusive

Chalupa L. M. and his colleagues concluded from intraocular injections of 2-amino-4-phosphonobutyric acid (APB), an agonist for class III metabotropic glutamate receptors, that glutamatergic signaling from ON bipolar cells, which exclusively express mGluR6, a class III receptor, played an important role in laminar refinement (Bodnarenko, S. R. and Chalupa, L. M., 1993; Bodnarenko, S. R. *et al.*, 1995). Based on the findings that the dendrites of more RGCs remained bilaminated in APB-treated eyes, they concluded that glutamatergic synaptic transmission from ON bipolar cells was important in laminar refinement. This conclusion is challenged by later results from mGluR6 knockout mice in which laminar stratification patterns appear normal (Tagawa, Y. *et al.*, 1999). One possibility that may reconcile these two different conclusions is that the membrane potential of the ON bipolar cells would be different in the two cases. In neither the APB nor mGluR6 mutant retinas should there be light responses in ON bipolar cells. However, in the APB-treated eyes, ON bipolar cells would be hyperpolarized. In mGluR6 mutant retinas ON bipolar cells would be depolarized. Further experiments will be needed to resolve this apparent inconsistency.

Chalupa L. M. *et al.* (1998) proposed two possible general synaptic mechanisms for the regulation of RGC dendritic stratification and the maturation of

the ON–OFF pathway. In the first model, they assumed that RGCs synapse functionally with only ON or OFF bipolar cells in early postnatal development, although the dendrites ramify in both the inner and outer IPL (Figure 4(a)). These asymmetrical inputs from ON or OFF bipolar cells could instruct those bilaminated RGCs to sever uninnervated dendrites during later postnatal development (Bodnarenko, S. R. *et al.*, 1995). If this were the case, one would expect to find RGCs stratified in both the inner and outer IPL but only respond to the onset or offset of light stimulation in early postnatal developing retina. Recent results obtained from simultaneous patch clamp and morphological recordings of ferret RGCs revealed that all RGCs with dendrites ramifying in both the inner and outer IPL responded to both the onset and offset of light in both young and adult animals, indicating that bilaminated RGCs are innervated by both ON and OFF bipolar cells (Wang, G. Y. *et al.*, 2001). Consistent with these results, intraocular injection of APB or light deprivation increased both the ON–OFF responsive and bilaminated RGCs in cat (Bodnarenko, S. R. and Chalupa, L. M., 1993; Bodnarenko, S. R. *et al.*, 1995; Bisti, S. *et al.*, 1998) and mouse (Tian, N. and Copenhagen, D. R., 2003) retina, respectively. Thus, it appears unlikely that an asymmetry of ON and OFF synaptic inputs is responsible for the elimination of exuberant processes in immature RGCs.

In the second model, it was assumed that synaptic transmission from bipolar cells triggers an intrinsic program in bilaminated RGCs leading to the retraction of one or another set of their dendritic processes (Figure 4(b)). This model relies on cell-specific intrinsic genetic programs that activate differential pruning of an individual cell's dendrites in either sublamina *a* or *b*. No molecular or genetic mechanisms that would mediate this selective pruning have been identified. Although the direct causal link between visual signaling and the molecular or genetic mechanisms that mediate selective proving has not been elucidated, brain-derived neurotrophic factor (BDNF) acting at TrkB receptors appears to play an important role in this proving (Landi, S. *et al.*, 2007; Liu, X. *et al.*, 2007).

1.24.1.1.4 Light deprivation alters the normal developmental sequence of excitatory and inhibitory synaptic inputs to retinal ganglion cells

In rodents, most of the molecular machinery required for synaptic transmission between retinal neurons develops during the time from birth until eye opening. Below we will focus on synaptic properties that reflect light-dependent regulation of the strength of synaptic inputs to RGCs after eye opening Specifically, the expression of glutamate *N*-methyl-D-aspartate (NMDA) receptors on RGCs and the rate of spontaneous excitatory and inhibitory

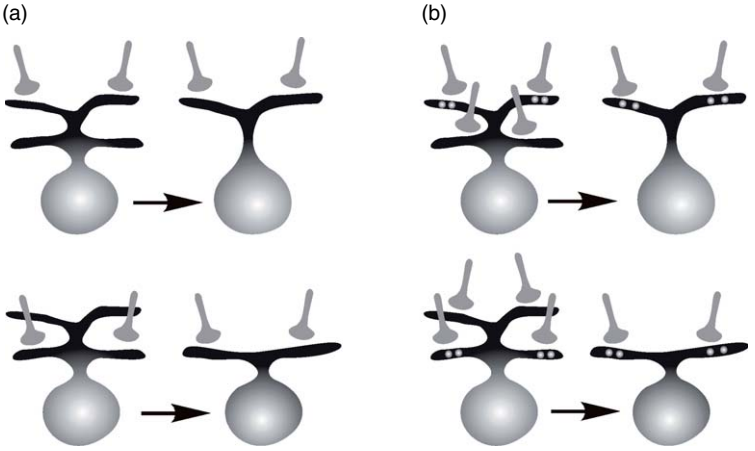

Figure 4 Schematic diagram illustrating possible mechanisms that underlying retinal ganglion cell (RGC) dendritic stratification. (a) Asymmetric afferent innervation model. RGC have their dendrites initially bi-laminated in both ON and OFF sublamina of inner plexiform layer and have asymmetric synaptic inputs. During development, dendrites that receive afferent inputs are maintained, whereas those do not receive afferent input are eliminated. (b) Intrinsic program model. Signal inputs from both ON and OFF bipolar cells trigger an intrinsic program in the bi-laminated RGCs, leading to elimination of the dendrites in either ON or OFF sublamina. Adapted from Xu, H. P. and Tian, N. 2004. Pathway-specific maturation, visual deprivation, and development of retinal pathway. Neuroscientist 10, 337–346, with permission from SAGE publications Inc.

synaptic inputs to RGCs are altered as a function of age after the time of eye opening in rodents. Light deprivation strongly influences all of these developmental events.

In mammalian retinas, neurogenesis and synaptogenesis follow similar maturational templates. During development, RGCs are the first neurons to differentiate, followed by cones, amacrine, and horizontal cells (HCs), and then rods, bipolar cells, and finally Müller cells. Morphologically identified conventional synapses between amacrine and ganglion cells in the IPL appear early during postnatal development. Cones and rods establish synaptic connectivity with horizontal and bipolar cells and then bipolar cells form ribbon synapses with amacrine and ganglion cells. At this time a synaptic link is completed that is necessary to elicit light responses in RGCs (Maslim, J. and Stone, J., 1986; Nishimura, Y. and Rakic, P., 1987). In rodents, the initial synaptic connections between amacrine and ganglion cells (conventional synapses) are established in the first postnatal week and the synaptic connections between bipolar and ganglion cells (ribbon synapses) begin forming around 10 days after birth (Fisher, L. J., 1979; Marquardt, T. and Gruss, P., 2002). Synapto-genesis continues for 2–3 weeks after the establishment of the synaptic connections from photoreceptor to RGCs (Figure 5(b)). In mice, the density of conventional synapses in the IPL rapidly increases in the second postnatal week from 85 synapses/1000 μm^3 at P3–10 to 223 synapses/1000 μm^3 around the time of eye opening (P11–15), which is very close to the adult level (250 synapses/1000 μm^3). The density of ribbon synapses in the IPL, in contrast, is low around the time of eye opening (45 synapses/1000 μm^3) and increase about 2.5-fold 3 weeks after eye opening to reach the adult level (113 synapses/1000 μm^3).

Physiologically, the percentage of rat RGCs having glutamate-activated NMDA receptor responses increases from birth until the time of eye opening after which this percentage, and the average amplitude of glutamate-induced NMDA currents, declines (Guenther, E. *et al.*, 2004). The percentage of RGCs with NMDA receptor-mediated responses in rats dark reared until P30 was almost double that of animals raised in cyclic light (96% vs. 47% in the cyclic-reared rats; Guenther, E. *et al.* 2004). Dark rearing appeared to delay the reduction in RGCs with NMDA receptor responses as the percentage dropped to 42% in those dark-reared animals that

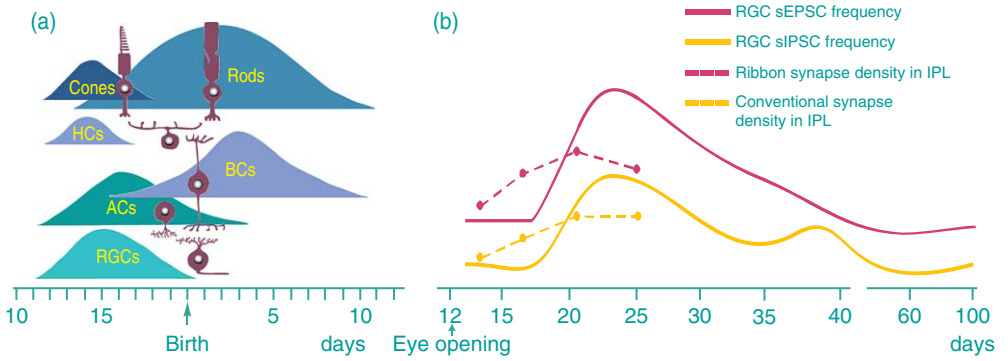

Figure 5 Neurogenesis and synaptogenesis in developing retina. (a) Neurogenesis in rodent retina begins before birth and is largely completed shortly after birth. There are roughly two waves in retinal neurogenesis. The differentiation of retinal ganglion cells (RGCs), horizontal cells (HCS), amacrine cells (ACS), and cones starts early during prenatal development and completes mostly before birth. The differentiation of rods and bipolar cells (BCS), however, starts shortly before birth and continues for 1–2 weeks after birth. (b) Synaptogenesis of mouse retina starts before eye opening and continues for several weeks after eye opening. The density of both ribbon and conventional synapse in inner plexiform layer reaches the peak at the age of postnatal 21 (modified from Fisher, L. J. 1979. Development of synaptic arrays in the inner plexiform layer of neonatal mouse retina. J. Comp. Neurol. 187, 359–372). The frequency of RGC spontaneous synaptic inputs increases with age and peaks around 2 weeks after eye opening (Tian, N. and Copenhagen, D. R., 2001). The curves show the relative cell populations, synaptic densities, and frequencies of spontaneous synaptic inputs as functions of time. The numbers indicate the prenatal and postnatal days of murine development. (Xu, H. P. and Tian, N., 2004) EPSC, excitatory postsynaptic current; IPL, inner plexiform layer; IPSC, inhibitory postsynaptic current. (a) Adapted from Young, R. W. 1985. Cell differentiation in the retina of the mouse. Anat. Rec. 212, 199–205. (b) Adapted from Tian, N. and Copenhagen, D. R. 2001. Visual deprivation alters development of synaptic function in inner retina after eye opening. Neuron 32, 439–443; and (Xu, H. P. and Tian, N., 2004); and Pathway-specific maturation, visual deprivation, and development of retinal pathway. Neuroscientist 10, 337–346.

were subsequently raised in cyclic light for 5 days. These findings demonstrate that the strength of glutamatergic inputs to RGCs can be regulated by light. Because NMDA receptors play such pivotal roles in both development and activity-dependent plasticity in other regions of the CNS, these light-dependent alterations of NMDA function are likely to be important for optimization of retinal functions.

The rate of vesicle-mediated spontaneous synaptic inputs into RGCs undergoes a maturational time-course that extends well past the time of eye opening; this maturational program is also regulated by visual inputs. After the time of eye opening the rates of spontaneous synaptic inputs from amacrine and bipolar cells onto RGCs continues to increase. In mouse retina, synaptic events associated with the random release of glutamate-filled vesicles from bipolar cells or gamma-aminobutyric acid (GABA)/glycine-filled vesicles from amacrine cells can be recorded in RGCs from about P7 (Johnson, J. *et al.*, 2003). Note that the glutamatergic events result from activation of α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors and not NMDA receptors. The rates of glutamate AMPA receptor-mediated spontaneous excitatory postsynaptic currents (sEPSCs) and GABA/glycine receptor-mediated spontaneous inhibitory postsynaptic currents (sIPSCs) remains constant for a few days after eye opening and then surge by four-fold around 2 weeks after eye opening. The rates of both sEPSCs and sIPSPs plateau by P60 (Figure 5(b)). The increase of the rate of RGC sEPSCs after eye opening might be partially attributed to a continuous increase of the number of synaptic contacts between bipolar and ganglion cells. The change in the rate of the RGC sIPSCs after eye opening, however, is more likely to reflect a change in the release probability of GABA/glycine of amacrine cells since the number of the conventional synapses in the IPL almost reaches the adult level at the time of eye opening.

Animals raised in darkness until P30 have significantly reduced rates of spontaneous RGC synaptic inputs. The frequencies of sEPSCs and sIPSCs fall to 35% and 48% of age-matched control animals raised in cyclic light/dark conditions, respectively (Tian, N. and Copenhagen, D. R., 2001). As with the NMDA-receptor-driven responses in RGCs, the rates of spontaneous events in dark-reared animals returned to those of cyclic light-reared mice after 6 days of cyclic light conditions. Dark rearing thus appears to delay the maturational increase in spontaneous synaptic inputs. Analysis of the amplitude and time-courses of the spontaneous synaptic currents strongly suggests that the suppression of RGC synaptic inputs induced by light deprivation does not influence the density of postsynaptic receptors or their single channel properties. Instead, it most likely reflects a reduction of the amount of glutamate released from presynaptic terminals (Tian, N. and Copenhagen, D. R., 2001) or the number of synaptic contacts. Future work will be required to determine how the release properties of amacrine and bipolar cells are regulated by visual inputs. Interestingly, even though the expression of NMDA receptors on RGCs and the release of vesicles are regulated by light, the peak expression of these two synaptic processes occurs at two different times. It is not known whether the developmental change in NMDA receptor expression regulates or triggers later occurring changes in release rates of glutamate and GABA/glycine.

1.24.1.2 Visual Experience Regulates the Maturation of Amacrine Cell Processes

Amacrine cells are interneurons in the inner retina. Amacrine cells extend their processes into different strata of the IPL where they can receive or transmit synaptic messages (see Masland, R. H., 2001; 2004, for an extensive structural analysis of amacrine cell classes and their processes, and Roska, B. and Werblin, F., 2001 for an example of the spatiotemporal processing served by amacrine cells). Using immunohistochemistry to identify structural arborization patterns of two classes of amacrine cell, separate groups have reported the development of serotonergic amacrine cells (Fosser, N. S. *et al.*, 2005) and cholinergic amacrine cells (Zhang, J. *et al.*, 2005) are influenced by visual stimulation.

1.24.1.2.1 Visual experience controls development of serotonergic amacrine cells in chick retina

In chicken retina, processes of serotoninergic (5-HT) amacrine cells arborize in two regions: an outer serotoninergic plexus is localized in the most distal layer of sublamina *a* of the IPL and an inner serotoninergic plexus is localized in the most proximal layers of sublamina *b* of the IPL. During postnatal development there is an age-dependent reduction in the number of processes in both the inner and the outer serotoninergic plexi, probably through developmental dendritic pruning. The serotonin amacrine cells of chicks raised in red-light from the time of hatching

had a significantly larger number of dendrites and varicosities. Thus, this change in 5HT amacrine cell dendritic arborization was interpreted as an inhibition of a visual activity-dependent dendritic pruning (Fosser, N. S. *et al.*, 2005). Although light seems to sculpt the serotonin amacrine cell processes, it is not known if the activity-dependent change in the morphology of serotonergic processes affects plasticity of visual functions in retina.

1.24.1.2.2 Visual deprivation reduces the number of detectable cholinergic amacrine cells and the extent of their processes in mouse retina

Visual activity reportedly modifies the maturation of mouse cholinergic amacrine cells during postnatal development (Zhang, J. *et al.*, 2005). In the vertebrate retina, cholinergic amacrine cells constitute a unique subpopulation of interneurons that contain acetylcholine and GABA and have processes confined to two narrow plexi in the IPL (Famiglietti, E. V., 1983; Vaney, D. I., 1984). Cholinergic amacrine cells mature relatively early in the retina. At birth, mouse cholinergic amacrine cells are already differentiated and their dendritic processes have projected specifically into the IPL. After birth, these cells undergo modest spatial rearrangement until 3 weeks after birth, which is characterized by the progressive increase of the thickness of the two cholinergic plexi and an increase of the space between the two plexi. Visual deprivation retarded the developmental processes occurring after eye opening, which resulted in thinner cholinergic plexi in the IPL, an interrupted mosaic of soma locations and reduced number of cholinergic immunoreactive cells. The effects induced by light deprivation could be reversed by returning the animals to normal dark/light conditions for 20–30 days (Zhang, J. *et al.*, 2005). In the adult retina, cholinergic amacrine cells synapse with bilaminated ON–OFF directional selective RGCs and mediate the directional selectivity of these RGCs (Famiglietti, E. V., 1991; Kittila, C. A. and Massey, S. C., 1997). In the immature retina, cholinergic synaptic transmission also plays an important role in mediating the spontaneous activity of RGCs during the early postnatal development before retina could respond to light (for review see Zhou, Z. J., 2001). Further study will be needed to determine whether visual deprivation affects these visual functions via the cholinergic amacrine cells.

1.24.2 Synaptic Circuitry Exhibits Plasticity in Response to Light and Dark Adaptation in Adult Retina

Visual stimulation regulates the refinement of retinal synaptic structures and functions in developing retina, a process which involves formation of new synapses and elimination of existing synapses and occurs over the course of days. In addition, visual stimulation can modify the strength and effectiveness of existing synapses in mature retina to alter the functional connectivity of retinal circuitry without any rewiring of the existing synaptic pathways. This process generally occurs in minutes and hours. We will term this type of plasticity as adaptive synaptic plasticity. Unlike the developmental synaptic plasticity, adaptive plasticity of synaptic wiring in mature retina is generally transitory and reversible and occurs at almost all level of retinal synaptic connections of many different species. We will first discuss microstructural changes and then cover functional alterations in synaptic connectivity and function.

1.24.2.1 Ambient Background Light Regulates Horizontal Cell Synapses and Gap Junction Coupling between Horizontal Cells

One of the most extensively studied examples of light-induced microstructural changes in retina is the transitory alteration of the synaptic processes linking photoreceptors and HCs. This has been documented primarily in fish retinas. Light can produce spinules, fingerlike protuberances of the HC dendritic membranes that project into the presynaptic terminals of photoreceptors. Spinulelike processes were first described in the rat hippocampus (Westrum, L. E. and Blackstad, T. W., 1962). In teleost retina, spinules are found in both outer plexiform layer (OPL) and IPL (Wagner, H. J., 1980; Dowling, J. E., 1987; Yazulla, S. and Studholme, K. M., 1992). They are most prominent on the dendritic terminals of HCs. During adaptation to brighter lights, numerous spinules arise from the terminal dendrites of HCs to invaginate the cone pedicles. Their presence may increase the contact area with the cone plasma membrane by up to 25% compared to the dark-adapted states. During dark adaptation, these spinules retract (Wagner, H. J., 1980).

The functional significance of HC spinules is still an open question. HCs are known to be involved in several different aspects of the visual process, such as

color signaling, spatial and temporal acuity, and the regulation of photoreceptor light sensitivity. It was suggested that HC spinules are the synaptic sites to generate biphasic chromatic responses in the retina. Support for this idea derives from the findings that the presence and absence of spinules is closely correlated with the development of biphasic chromatic responses in a class of cone HCs as well as the presence of color opponent responses in RGCs (see Wagner, H. J. and Djamgoz, M. B. A., 1993 for review). However, color-coding HCs are also present in other species that lack spinules completely (Simon, E. J., 1974), suggesting spinules might not be required for the chromatic signaling.

Both dopamine and glutamate are thought to act as neuromodulators to regulate spinule formation on HC dendrites, however multiple pathways may control their formation. The effect induced by light or exogenous dopamine on the spinule formation can be blocked most effectively by D1 antagonists (Kirsch, M. *et al.*, 1991; Behrens, U. D. *et al.*, 1992; Yazulla, S. *et al.*, 1996). Other studies suggested that dopamine receptor-associated mechanisms are probably not the only agents mediating the light-adaptive increase in spinule numbers since dopamine depletion or dopaminergic antagonists *in vivo* do not completely block the formation of spinules and the effect induced by dopamine is much weaker than that induced by light adaptation (Weiler, R. *et al.*, 1988; Kohler, K. *et al.*, 1990; Yazulla, S. *et al.*, 1996). Weiler R. *et al.* (1991) reported that activation of protein kinase C by phorbol esters promotes the formation of new HC spinules in dark-adapted animals, in retinas depleted of dopaminergic neurons and in synaptically isolated HCs, demonstrating that they have a direct action on the spinule-formation of these cells.

The dark-induced degradation of spinules may be controlled by glutamate released from photoreceptors. Glutamate or kainate application in isolated light-adapted retina effectively reduced the number of HC spinules to dark-adaptive levels (Weiler, R. *et al.*, 1988) probably through activation of AMPA receptors (Weiler, R. and Schultz, K., 1993). A more recent study suggested that calcium-influx through AMPA/kainite receptors during dark adaptation and subsequent activation of calmodulin-dependent protein kinase II (CaMKII) is an important step for spinule retraction (Schultz, K. *et al.*, 2004).

HCs have been found to be electrically coupled by gap junctions in virtually every vertebrate class studied. This coupling generally is between cells of the same subtype, that is, A-type HC to A-type HCs and B-type to B-type HCs in mammalian retina (see Webvision for details). Light adaptation regulates the conductance of intercellular gap junction coupling as revealed by the modulation of dye coupling from one injected cell to its neighbors and by the changes in receptive field size to light flashes. In rabbit retina, both A- and B-type HCs are uncoupled in the dark and receptive fields are relatively small. Increases of background illumination from roughly 0.25 log units above the threshold intensity for rods to approximately 1.5 log units above rod threshold resulted in increased dye coupling from an injected cell to its neighbors. Concomitantly, receptive fields enlarged. Further increases in background illumination reduced dye coupling and receptive field sizes to dark-adapted levels (Xin, D. and Bloomfield, S. A., 1999). Background light-induced changes in horizontal receptive field dimensions have been studied in nonmammalian retinas (Baldridge, W. H. and Ball, A. K., 1991). An extensive literature exists on the role of dopamine and other neuromodulators in regulating gap junctional conductance in both nonmammalian retina (see Witkovsky, P. and Dearry, A., 1992 for review) and mammalian retinas (see Witkovsky, P., 2004 for review).

1.24.2.2 Light and Dark Conditions Modify the Morphology of Bipolar Cell Axons

In the inner retina, bipolar cells are presynaptic to amacrine cells; amacrine cells, in turn, synapse back onto the bipolar terminals. In teleost retina, spinules evaginate from the terminals of the mixed rod–cone type of bipolar cell, and invaginate a substantial fraction of the presynaptic processes of amacrine cells. Yazulla S. and Studholme K. M. (1991) first described spinules on goldfish bipolar cell terminals in both sublaminas *a* and *b* of the IPL. Spinules of ON and OFF bipolar terminals responded oppositely to light and dark adaptation. Three-fold more of the mixed rod–cone ON bipolar terminals expressed spinules in the dark than in the light. In contrast, three-fold more OFF cone bipolar cells expressed spinules in the light versus the dark (Behrens, U. D. and Wagner, H. J., 1996).

Bipolar cells of mammals do not have spinules. However, mammalian rod ON bipolar cells also showed light/dark-related morphological changes at the surface of their synaptic terminals. Light-adapted axon terminals were round and smooth and exhibited more convexly curved synaptic membranes. In contrast, dark-adapted terminals had irregular contours, numerous dimples and a concave synaptic curvature (Behrens, U. D. *et al.*, 1998). Similar changes in

terminal morphology were observed in fish retinas (Yazulla, S. and Studholme, K. M., 1992; Behrens, U. D. and Wagner, H. J., 1996). Interestingly in rat retina, protein kinase C (PKC) immunoreactivity in light and dark was differentially localized in rod bipolar cells. In light-adapted rod bipolar cell axon terminals, PKC immunoreactivity was homogeneously distributed throughout the cytoplasm, whereas terminals from dark-adapted animals showed PKC immunoreactivity preferentially localized in the submembrane compartment and a reduced staining of the more central cytoplasm (Behrens, U. D. *et al.*, 1998).

1.24.2.3 Light and Dark Controls Gap Junction Coupling and Receptive Field Properties of Amacrine Cells

A large variety of amacrine cells provides both excitatory and inhibitory synaptic inputs to bipolar, ganglion as well as other amacrine cells (for review of subtypes see Webvision and Masland, R. H., 2001; 2004). AII amacrine cells, the most extensively studied amacrine cell in mammalian retina, connect rod-driven visual signals from rod bipolar cells to cone bipolar cells by forming glycinergic chemical synapses with OFF cone bipolar cells in sublamina *a* and gap junctional synapses with ON cone bipolar cells in sublamina *b* of the IPL (Famiglietti, E. V. and Kolb, H., 1975; Strettoi, E. *et al.*, 1992; 1994). AII amacrine cells also receive synaptic inputs from OFF cone bipolar cells (Strettoi, E. *et al.*, 1992; 1994; Sterling, P., 1995). This input accounts for nearly 40% of the chemical synaptic inputs from bipolar cells. Thus, AII amacrine cells receive and transmit both rod and cone signals. In addition, neighboring AII amacrine cells couple to each other through gap junctions (Famiglietti, E. V. and Kolb, H., 1975; Vaney, D. I., 1991; Strettoi, E. *et al.*, 1992). Intercellular coupling between AII amacrine cells can be modulated by background light. Coupling between AII amacrine cells and bipolar cells can be modulated by dopamine and nitric oxide (NO) released in the retina, both of which are regulated by light stimulation (see reviews of Witkovsky, P. and Dearry, A., 1992; Bloomfield, S. A., 2001).

By measuring the extent of neurobiotin found in neighboring neurons after injection into a single AII amacrine, Xin D. and Bloomfield S. A. (1997) demonstrated that there was dramatic increase in tracer coupling to both AII amacrine cells and cone bipolar following exposure to dim background lights. These dim background conditions increased the number of tracer labeled AII amacrine cells from 20, on average, in dark-adapted retinas to over 300 in dim backgrounds (Figure 6). As with HC tracer coupling

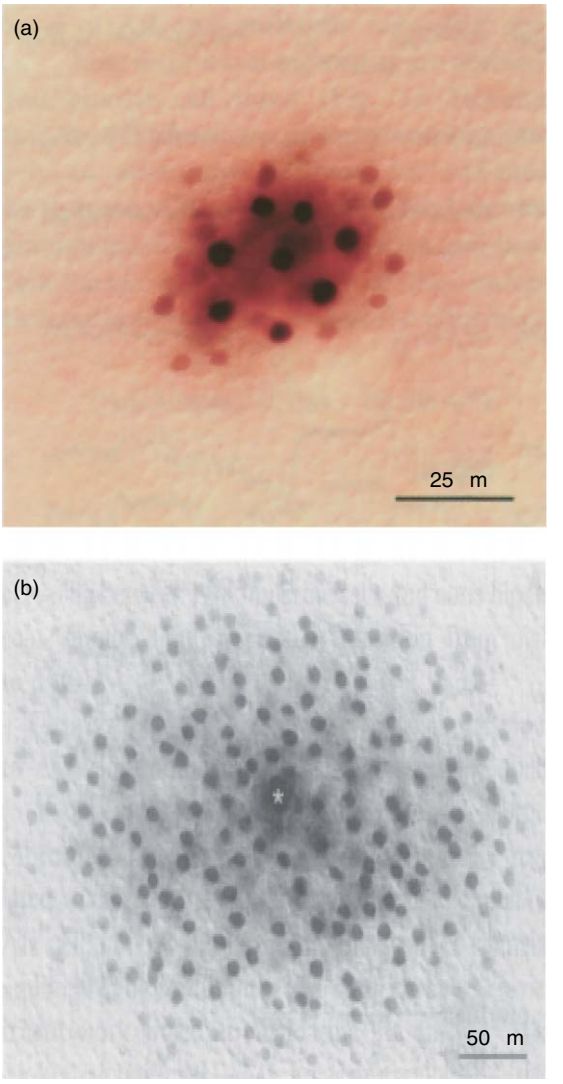

Figure 6 Light and dark controls gap junction coupling of AII amacrine cells. (a) Image of the tracer coupling pattern of AII amacrine cells in a dark-adapted retina following injection of neurobiotin into a single AII amacrine cell. The injected AII amacrine cell (center of the image) was well-coupled with seven surrounding AII amacrine cells to form an inner ring of eight darkly labeled AII amacrine cells and lightly coupled with other 10–15 more remote AII amacrine cells. (b) Image of tracer-coupled AII amacrine cells in a retina exposed to a log −5.5 intensity full-field illumination for 1 h prior to the injection of neurobiotin. The injected AII amacrine cell (star) was well coupled with many surrounding AII amacrine cells. Adapted from Bloomfield, S. A. 2001. Plasticity of AII amacrine cell circuitry in mammalian retina. Prog. Brain Res. 131, 185–200, with permission from Elsevier.

brighter backgrounds reduced the number of coupled cells back to the number found in dark-adapted retinas.

Background lights also regulated functional aspects of the receptive fields of the AII amacrine cells. In dark-adapted retina, AII amacrine cell receptive fields display a stereotypic ON-center-OFF-surround organization with a relatively small ON-center, extending only approximately 60–80 μm across the retina, and an OFF-surround extending 100–130 μm. The small receptive field of a dark-adapted AII amacrine cell reflects their narrow dendritic arbors and coupling to a relatively small group of neighboring AIIs. Dim background lights, which produced a so-called light-sensitized condition, increased the size of their ON-center and OFF-surround receptive fields. The ON-center receptive field measures approximately 6–7 times the size of the center receptive fields of AII amacrine cells in dark-adapted retinas. AII amacrine cells characterized in light-adapted retinas showed ON-center and OFF-center responses but did not display OFF-surround activity (Xin, D. and Bloomfield, S. A., 1999).

1.24.2.4 A Possible Mechanism by Which Light and Dark Could Regulate Synapse Strength Between Bipolar and Amacrine Cells

An activity-dependent modulation of the feedforward-feedback synapses between bipolar axon terminals and amacrine cell processes has been revealed in goldfish retina (Vigh, J. *et al.*, 2005). Although this modulation has not been shown to be regulated by light *per se*, this mechanism could easily control neurotransmitter output from bipolar cells under different lighting conditions. This recent study showed that synaptically released glutamate from goldfish Mb-type bipolar cell terminals activates mGluR1 receptors on amacrine cells. Activation of the mGluR1 receptors occurred only after bipolar cells were strongly depolarized briefly or depolarized for prolonged periods. Once mGluR1 was activated, it boosted the reciprocal negative feedback by enhancing GABA release from amacrine cells to the bipolar cells. Therefore, it was proposed that after prolonged stimulation reciprocal synapses between GABAergic amacrine cell and bipolar cells undergo an mGluR1-mediated long-term plasticity that lasts for several minutes. This mGluR1-mediated long-term potentiation of the GABAergic reciprocal feedback participates in downscaling the output of very active ON-type bipolar cells.

1.24.2.5 Light Can Regulate the Expression of α-Amino-3-Hydroxy-5-Methylisoxazole-4-Propionic Acid-Glutamate Receptors on Retinal Ganglion Cells

Background light is known to decrease the amplitude and sensitivity of light-evoked ganglion cell responses (Green, D. G. *et al.*, 1975; Green, D. G. and Powers, M. K., 1982). Although some of this desensitization and response compression reflects the behavior of photoreceptors, a significant component, particularly at dimmer intensities, is due to changes in the signaling properties of the inner retina (Green, D. G. and Powers, M. K., 1982). Given that the expression of AMPA-type glutamate receptors can be regulated by activity in cortical and hippocampal neurons (Malinow, R. and Malenka, R. C., 2002; Lu, H. C. *et al.*, 2003; Takahashi, T. *et al.*, 2003; Tomita, S. *et al.*, 2004), it is a intriguing idea that light adaptation could regulate glutamate receptor expression on retinal neurons (Thoreson, W. B. and Witkovsky, P., 1999). Xia Y. *et al.* (2006) reported that 8 hours or more of dark adaptation upregulated the rate of AMPA receptor cycling in ON RGCs. While net surface expression of AMPA receptors was not shown to be linked directly to changes in the amplitude and sensitivity of light-evoked responses, this study is a first step to demonstrate a light-dependent functional rewiring of synaptic inputs to retinal neurons that could be controlled by the trafficking of postsynaptic neurotransmitter receptors to locations opposite presynaptic release sites.

1.24.2.6 Light and Dark Adaptation Controls Receptive Field Organization of Retinal Ganglion Cells

Ganglion cell receptive field center sizes have been shown to increase with dark adaptation (Peichl, L. and Wassle, H., 1983; DeVries, S. H. and Baylor, D. A., 1997). Surround fields of RGCs become weaker with dark adaptation (Barlow, H. B. *et al.* 1957; Jensen, R. J., 1991; Muller, J. F. and Dacheux, R. F., 1997). It has been argued that the loss of surround fields in darkness is a tradeoff that allows greater spatial summation at the cost of reduced visual acuity. The cellular mechanisms responsible for these receptive field alterations have not been worked out. Interestingly, the decreased sensitivity of RGC surround fields with

dark adaptation is opposite to that of AII amacrine cells in which surrounds were more prominent in dark-adapted conditions. The dissimilarities underscore the idea that multiple activity-dependent mechanisms contribute to the functional structure of the receptive fields of retinal neurons.

1.24.3 Survival Rewiring of Retinal Circuits

Mature retinal synaptic circuits can show structural adjustments as a result of degenerative conditions or dysfunctions caused by the loss or mutation of key proteins in phototransduction or synaptic signaling pathways. This seemingly compensatory rewiring may or may not follow the original paths of the synaptic wiring of normal retina, but is nonetheless often considered a way that the retina readjusts itself to maintain some semblance of visual signaling.

Examples of this compensatory synaptic rewiring are the instances of the sprouting or rearrangement of synaptic connections between photoreceptors and bipolar cells in retinal degenerations or the sprouting of dendritic processes of second-order retinal neurons resulting from retinal detachments or loss of visual signaling from rods and cones. Although retinal rewiring under pathological conditions is not usually considered to be plasticity, this process is generally accompanied with changes in expression of specific proteins and/or transcriptional factors, which resemble the normal developmental processes. Neural remodeling that includes loss and sprouting of dendritic processes, degeneration of presynaptic structures and cellular reorganization has been extensively reviewed by others (Marc, R. E. *et al.*, 2003; Strettoi, E. *et al.*, 2003). Below, we will highlight some of the examples of synaptic rewiring in which new synaptic contacts are formed or in which new dendrites or axons sprout in a manner that suggests an attempt by the retina to either maintain former connections or search for new ones.

1.24.3.1 Rewiring of Synaptic Connections in Outer Retina in Response to Photoreceptor Degeneration or Loss of Synaptic Signaling

The extent and form of synaptic rewiring in the OPL seems to depend on the severity and time course of the degeneration of rods and cones. In mice with rapid rod and cone degeneration, such as *rd/rd*, rod bipolar dendrites are never fully formed (Strettoi, E. and Pignatelli, V., 2000; Strettoi, E. *et al.*, 2002). In these mice, rod bipolar dendritic processes retract and eventually disappear. Dendritic processes of rod-driven HCs in *rd/rd* mice also retract and vanish. However, these cells transiently sprout processes that reach into the inner retina and arborize. Cone bipolar cells progressively degenerate. In $crx^{-/-}$ mice, which have a slower rate of rod degeneration than *rd/rd* mice and have slower cone degeneration as well, rod and cone bipolar cells initially form dendritic processes in the OPL, but then these are degraded leading to loss of all dendrites and eventual bipolar cell death. HCs show the same morphological changes as in *rd/rd* mice but over a longer time period (Pignatelli, V. *et al.*, 2004).

In the P347L transgenic pig, a rhodopsin mutation that produces a prolonged degeneration and loss of rods but a slower and less severe loss of cones, rod bipolar cells are seen to extend dendritic processes to cone synaptic terminals (Peng, Y. W. *et al.*, 2000). The interpretation of the presence of these new processes, rarely seen in wild-type animals, is that the bipolar cells have tried to establish ectopic synaptic contact with surviving photoreceptors. The formation of similar ectopic synapses was observed in degenerative RCS rat retina, in which rods and cones develop normally initially and then there is a progressive loss of rods after about 3 weeks of age (Peng, Y. W. *et al.*, 2003). Therefore, the formation of ectopic synapses can be considered an activity-dependent rewiring of normally developed retina. Consistent with this idea, Haverkamp S. *et al.* (2006) found that cone bipolar cells form ectopic synapses with rods in a transgenic (*CNGA3*−/−) mouse model, which loses the function of cones with minimum loss of cone photoreceptors. In contrast, input-deprived rod bipolar cells form ectopic synapses with functional cones in *Rho*−/− mice, which loses the rod function without significant loss of rod photoreceptors. In addition, neither cone nor rod bipolar cells form ectopic synapses with inoperable cones or rods in the *CNGA3*−/−*Rho*−/− mouse. Sprouting of denditric processes from HCs and ON bipolar cells into the ONL and formation of ectopic synapses is also observed in mice lacking the essential synaptic protein bassoon in photoreceptors (Dick, O. *et al.*, 2003), and in mice with a mutant form of the calcium channel (α1f) that regulates exocytosis of glutamate from photoreceptors (Chang, B. *et al.*, 2006).

1.24.3.2 Survival Plasticity of Retinal Wiring in Retinal Detachments

Retinal detachment in mature animals triggers a reorganization of retinal circuits that include sprouting of bipolar and HC dendrites into the ONL. In experimental retinal detachments, rod bipolar cell processes grow into the ONL within 1 day. These outgrowing rod bipolar cell dendrites could persist in the ONL for a long time even after the detached retina was reattached (Lewis, G. P. *et al*., 1998; 2002; Fisher, S. K. and Lewis, G. P., 2003). Interestingly, most of these dendrites appear to remain connected to withdrawn rod terminals even though most of these dendrites have lost their deep synaptic invaginations. Thus, the outgrowth of rod bipolar cell dendrites appear to be target-directed. The synaptic terminals of both rods and cones, in contrast, change their morphology to appear more like synapses in immature retina (Erickson, P. A. *et al*., 1983; Linberg, K. A. and Fisher, S. K., 1990; Lewis, G. P. *et al*., 1998). Therefore, this remodeling of photoreceptor-bipolar cell synaptic connections might share the same underlying regulatory mechanisms for that of normal development. Upon reattachment of the detached retina, rod axons appear to regrow into the OPL and sometimes overshoot to growing into the inner retina (Fisher, S. K. and Lewis, G. P., 2003). This phenomenon has also been identified in early developing retina (Johnson, P. T. *et al*., 1999). The morphology of HCs also changes dramatically in the detached retina. Dendritic processes extend into the ONL and axonal-like processes may extend into proximal retina.

Little is known about the effect of retinal detachment on the inner retinal neurons. One recent study revealed that both gene expression and dendritic structure of RGCs are also affected in detached retina. The expression of both neurofilament protein and GAP43, a molecule associated with axon growth and targeted synaptogenesis during development, are upregulated in RGCs after detachment (Coblentz, F. E. *et al*., 2003). Thus, the effects of synaptic rewiring induced by retinal detachment extend across the entire neural network of the retina.

Glossary

antidromic activation Induction of an action potential in a neuronal soma by triggering a spike in its axon and allowing it to propagate in a retrograde direction.

bistratified Having a dendritic arbor occupying two distinct levels of the inner plexiform layer.

costratification The arborization of the dendrites of two distinct cell types at the same level of the inner plexiform layer.

homologous cell types Cell types in different species sharing a common evolutionary origin.

monostratified Having a dendritic arbor restricted to a single level of the inner plexiform layer.

paramorphic pair A pair of neuronal cell types differing from one another mainly at the level of dendritic stratification, but otherwise more similar to one another than to other types.

retinal eccentricity Distance of a retinal location from the fovea or other site of maximum acuity.

retinal ganglion cell A neuron of the vertebrate retina that contributes an axon to the optic nerve.

1.25.1 Introduction

The eye communicates with the brain exclusively through the axons of retinal ganglion cells (RGCs). Since the seminal work of Ramon y Cajal in the late nineteenth century, it has been recognized that RGCs are remarkably heterogeneous in form, especially in the depth of stratification and the lateral spread of their dendrites in the plane of the retina. During the latter half of the twentieth century, single

unit recordings paved the way for an appreciation of the diversity these cells also exhibit in their functional properties. The emergence of anterograde and retrograde axoplasmic tract tracing methods revealed that retinofugal axons were distributed to a bewildering array of central visual targets and that individual retinorecipient targets received input from subsets of RGCs.

It has long been recognized that the structure, function, and central projections of RGCs are highly correlated. An enduring goal of visual neurobiologists has been to exploit these correlations to devise a comprehensive classification of ganglion cells and to reveal the unique roles of individual types in visual behavior and perception. For a comprehensive review of the intellectual roots and early history of this effort, the reader is referred to the excellent book by Stone J. (1983). In this chapter, an overview of more recent progress in this area has been presented. It is intended to serve as a bridge between the preceding chapters on selected RGC types, and the chapters to follow, which consider individual central visual nuclei and their functional roles.

Those courageous enough to make even a brief foray into the labyrinth of ganglion cell taxonomy quickly recognize that the literature in this area is large, unruly, and extraordinarily difficult to wrestle into coherency. There are wide disparities among studies in the empirical basis for classification, in the numbers of types defined, and in the properties and nomenclature applied to those types. This is true even within a single species and even when limiting consideration to only morphological or only physiological studies. The tenuous linkage between structural and functional observations further complicates the matter. Finally, only tentative steps have been made toward achieving the long-term goal of itemizing fully the RGC types providing input to each of the retinorecipient subnuclei of the brainstem and diencephalon. Much of the evidence in this area is fragmentary and defies generalization across mammalian orders.

Given the complexity, the focus in this chapter is on broad organizational principles and informative examples rather than a comprehensive itemization of the available data. The chapter begins with survey of some general principles of ganglion-cell taxonomy and of the evolution of techniques for characterizing and classifying these cells. It then describes a handful of RGC types that appear to be highly conserved across mammalian phylogeny and summarizes their salient characteristics. I will review the current state of knowledge about the range of central targets innervated by retinofugal axons, and relate these, where possible, to specific subtypes of RGCs.

1.25.2 Ganglion Cell Types

Before grappling with the complexities of individual ganglion cell types in diverse retinas, it is worth summarizing some general principles that have emerged from the work of the past several decades. These are covered in further detail in several fine reviews, theoretical manuscripts, and books (Rowe, M. H. and Stone, J., 1977; Wässle, H., 1982; Rodieck, R. W. and Brening, R. K., 1983; Stone, J., 1983; Wässle, H. and Boycott, B. B., 1991; Rodieck, R. W., 1998; Masland, R. H., 2001a). First, it now seems beyond question that mammalian retinas contain more than a dozen distinct types of RGCs. Any concerted effort at classification of these cells requires analysis of the systematic covariation of as many features of these cells as practical (Rowe, M. H. and Stone, J., 1977; Rodieck, R. W. and Brening, R. K., 1983; Rodieck, R. W., 1998). These have traditionally focused on structural and functional data, but future studies can be expected to incorporate genomic and proteomic analyses as well. In retinas with central retinal specializations (i.e., a fovea, area centralis, or visual streak), it is of particular importance to appreciate the enormous influence of retinal location (i.e., eccentricity), which, in turn, specifies local ganglion cell density. This density dictates the spatial precision or the grain of each type's representation by specifying how widely a member of that type deploys its dendrites across the retinal surface to sample the array of bipolar (and amacrine) cell inputs. In primate, cat, and rabbit retinas, cells of a single type exhibit radical eccentricity-dependent rescaling in the sizes of dendritic and receptive fields. In fact, this systematic variation in size within a type is often much greater than that between distinct types intermingled at a single retinal location.

There is broad consensus that the process of identifying biologically meaningful cell types consists of identifying, either implicitly or explicitly, clusters of points in multidimensional parameter space, with each point representing a single cell (Rowe, M. H. and Stone, J., 1977; Stone, J., 1983; Rodieck, R. W. and Brening, R. K., 1983; Rodieck, R. W., 1998). Types that are discovered according to these principles have proven, without any obvious exception, to form regular mosaics, with cells spaced from one another and

their dendritic field profiles arranged so as to efficiently tile the retinal surface (see Chapter Mosaics, Tiling and Coverage by Retinal Neurons for review).

1.25.2.1 Morphological Classification

Classification of RGCs by their structural features is most advanced in retinas of rabbit, cat, mouse, and primate, and this chapter thus focuses mainly on data from these species. The broad outlines of RGC taxonomy were established in early studies using Golgi, Nissl, and neurofibrillar stains (see Stone, J., 1983 for review). Progress accelerated significantly with the introduction of methods for intracellular dye filling. Initially this was achieved by iontophoresis through intracellular sharp electrodes in fixed or living tissue (e.g., Buhl, E. H. and Peichl, L., 1986; Dann, J. F. and Buhl, E. H., 1987; Dacey, D. M., 1989; Pu, M. L. and Amthor, F. R., 1990a; 1990b; Rodieck, R. W. and Watanabe, M., 1993). More recent innovations include the use of ballistic particle-mediated delivery of lipophilic fluorescent dyes or of genes coding for fluorescent proteins (e.g., Rockhill, R. L. *et al.*, 2002; Sun, W. *et al.*, 2002a; 2002b); various photofilling methods (e.g., Rockhill, R. L. *et al.*, 2002; Dacey, D. M. *et al.*, 2003); and the development of transgenic mouse strains in which marker proteins are expressed under the control of cell-type-specific promoters (Badea, T. C. and Nathans, J., 2004; Hattar, S. *et al.*, 2002; 2006; Kong, J. H. *et al.*, 2005; Coombs, J. *et al.*, 2006).

The two morphological parameters that have proven of the greatest power for RGC classification are the dendritic field size (when considered in association with eccentricity, as noted above) and the depth of stratification of dendrites within the inner plexiform layer (IPL). The latter parameter is typically quantified as a percentage of the distance between the inner and outer boundaries of the IPL, but distinctions between certain similar types require greater precision. This can be achieved by assessing the stratification of the RGC in relation to that of cells with well-established and narrow stratification in the same or adjoining sublayers (e.g., Famiglietti, E. V., 1992; Berson, D. M. *et al.*, 1998; Yamada, E. S. *et al.*, 2005). A particular useful fiducial marker of this sort is the paired bands of immunostaining for choline acetyltransferase (ChAT), with each band formed by dendrites of one of the two types of starburst amacrine cells (ON or OFF). Beyond dendritic stratification and field size, other useful parameters of dendritic structure include the number and density of branch points, branch angles, and various higher-order statistics capturing the architecture of the dendritic profile. The dimensions of the soma and thickness of the axon can be very informative for a few types, but for most others the overlap with other types on these measures is too great for them to be of much value.

Even with the application of powerful staining methods and quantitative morphometry in well-studied retinas, and despite years of concerted effort by many laboratories, no consensus exists about the precise number of structural RGC types or about the validity of many of the specific types proposed. This is partly because many of the studies conducted to date have been more descriptive than quantitative and have drawn upon a few examples of individual proposed types rather than a large sample obtained at many eccentricities. A few attempts have been made using objective cluster analysis to analyze multiparametric data sets on the full RGC population (Badea, T. C. and Nathans, J., 2004; Kong, J. H. *et al.*, 2005; Coombs, J. *et al.*, 2006). However, the collection and entry of large numbers of parameters for a large set of RGCs is extremely labor intensive, and most of the progress made to date has been made with less comprehensively quantitative approaches on large libraries of filled cells or by narrowing the scope to subpopulations of RGCs selected on the basis of cell size, retrolabeling from specific targets, or other distinctive features.

Many RGC types occur as paramorphic pairs (Famiglietti, E. V., Jr. and Kolb, H., 1976). These consist of two subtypes differing from one another in the stratification of their dendrites, but otherwise resembling one another far more than they do other RGC types. In such cases, one subtype arborizes in the outer (OFF) sublayer of the IPL and the other in the inner (ON) sublayer. Because their dendrites stratify in a relatively narrow plane within the IPL, these paramorphic types are said to be monostratified. Other ganglion cell types are monostratified but appear to lack a paramorphic partner. These may arborize in the ON sublayer, the OFF sublayer, or at the boundary between them. Still other types are broadly stratified or bistratified, with dendrites in both ON and OFF sublayers. Examples of all of these arrangements have been observed in every well-studied mammalian retina. Stratification is predictive of receptive-field center type, so that monostratified cells are generally known or presumed to be either ON or OFF center. In contrast,

monostratified RGCs stratifying at the ON/OFF sublayer border, as well as broadly stratified or bistratified RGCs, are known or presumed to have mixed ON–OFF receptive field centers.

1.25.2.2 Physiological Classification

The functional properties of RGCs have been most fully studied in cats, rabbits, and primates and attempts at systematic classification have progressed furthest in these species. Until very recently, functional information has come mainly from single-unit studies, with recordings made *in vivo* either intraocularly from the RGC somas or intracranially from their axons in the optic tract. The introduction of *in vitro* methods, and especially of the multielectrode array method, has greatly accelerated the rate at which recordings, especially of relatively rare types, can be obtained and has already been exploited to classify mammalian RGCs (Devries, S. H. and Baylor, D. A., 1997).

Most of the functional parameters that have been exploited in physiological classification efforts consist of various aspects of receptive-field organization. Among those most widely exploited are the size and sign (ON, OFF, or ON–OFF) of the receptive field center, the time course of response to a step in illumination (sustained or transient), and the linearity of spatial summation. Selectivity for stimulus wavelength, direction of motion, or orientation has often helped to identify specific RGC types. Biophysical properties such as peak firing rate (briskness), spike shape, and axonal conduction velocity have also proven useful in many cases, and the analysis of specific voltage-gated conductances may prove to be productive in intracellular studies (O'Brien, B. J. *et al.*, 2002).

1.25.2.3 Structure–Function Correlations

Cell types identified on the basis of morphological or physiological features alone far outnumber those for which both structure and function are known. When the form and function of single cells cannot be made directly, provisional associations can be made by exploiting well-established correlations between structural and functional features. For example, dendritic field areas are generally predictive of receptive field center sizes; dendritic stratification can be used to infer receptive-field center sign (ON, OFF, or ON–OFF); and axon caliber determines conduction velocity. Patterns of central projection can be used to indirectly link form and function because they can determined in anatomical experiments using retrograde labeling, and in physiological ones by antidromic activation. For central targets receiving input mainly from one or a few types, such correlations can be very informative. However, convincing linkages between form and function generally require intracellular recording followed by dye filling. The technical demands of such work are substantial and remain a significant impediment to developing a comprehensive integrative taxonomy.

1.25.2.4 Homologous Retinal Ganglion Cell Types in Mammalian Retinas

As efforts to devise robust classification schemes for RGCs have advanced in individual species, similarities between certain types in different species have encouraged the view that at least some of these types may be homologous, with lineages traceable to a common progenitor type in the last shared ancestor of the species in which the types are observed. In principle, some types might even be shared by all mammals or even by all vertebrates. Examples of types for which such homology might be obtained are discussed below. However, the evidence for such homologies is relatively scanty even in the clearest cases, and it is far from obvious how far this approach can be pushed. There is no help to be found in the fossil record. For extant retinas, the difficulty is partly that we lack sufficient data on enough cells in a large enough number of species. It may also be because homologous types have undergone such significant remodeling in the course of mammalian evolution that the common features are obscured. Finally, it is possible that entirely new RGC types have emerged independently during mammalian evolution, perhaps many times in multiple mammalian lineages. Efforts to seek equivalents of every known type across all mammals may thus be an exercise in futility.

1.25.3 A Survey of Some Conserved Ganglion Cell Types

Intensive work on ganglion cell classification has been ongoing for more than 30 years. There is thus a wealth of data concerning the structure, function, and projections of these cells in many mammalian species. Much of this information is qualitative or

fragmentary, and thus resists integration across observational domains (structure, function, and projection) and across species. A comprehensive survey of the literature relevant to individual species is beyond the scope of this chapter, and the reader is referred to Table 1 for a listing of selected papers on RGC types based on morphological, physiological, or combined structural and functional data. In this chapter, the focus is on a handful of types that most closely approach the ideal implicit in ganglion cell taxonomy, namely, types for which structure and function have been convincingly correlated and which have apparently been conserved in retinas of diverse mammalian orders.

1.25.3.1 Melanopsin-Expressing Retinal Ganglion Cells

The type most closely approaching this ideal is the melanopsin-expressing intrinsically photosensitive retinal ganglion cell (ipRGC). The salient characteristics of this type include their expression of the novel opsin melanopsin, their intrinsic photosensitivity, and their projections to brain regions mediating so-called nonimaging-forming visual functions. This cell type is the subject of the Chapter Melanopsin Cells, to which the reader is referred for details concerning their discovery, morphology, functional properties, and behavioral roles (see also Chapter The Suprachiasmatic Nucleus).

To summarize briefly, studies in rodents demonstrated that a rare population of ganglion cells (<2% of all RGCs) express melanopsin, project to the circadian pacemaker in the suprachiasmatic nucleus (SCN), and are intrinsically photosensitive (Provencio, I. *et al.*, 2000; 2002; Gooley, J. J. *et al.*, 2001; Berson, D. M. *et al.*, 2002; Hannibal, J. *et al.*, 2002; Hattar, S. *et al.*, 2002; Warren, E. J. *et al.*, 2003). These cells have a large, very sparsely branching dendritic arbor that stratifies narrowly in the outermost sublayer of the IPL (Berson, D. M. *et al.*, 2002; Hattar, S. *et al.*, 2002; Provencio, I. *et al.*, 2002; Hannibal, J. *et al.*, 2002; Coombs, J. *et al.*, 2006). This cell type appears highly conserved among mammals. It is present not only in several other rodents (blind mole rat: Hannibal, J. *et al.*, 2002; hamster: Sollars, P. J. *et al.*, 2003; Morin, L. P. *et al.*,

2003) but also in strikingly similar form in the primate retina (giant RGCs; human: Provencio, I. *et al.*, 2000; Rollag, M. D. *et al.*, 2003; Dacey, D. M. *et al.*, 2005; macaque: Dacey, D. M. *et al.*, 2005; see also Pu, M., 1999 for relevant data in cat). It should be noted, however, that the primate retina has two subtypes of melanopsin-expressing RGCs. One of these corresponds closely in form to the rodent type already described, except that the cell body is usually displaced to the inner nuclear layer (Dacey, D. M. *et al.*, 2005). The second type has a dendritic arbor stratifying within the innermost IPL. This type, which is also intrinsically photosensitive (Dacey, D. M. *et al.*, 2005), appears to have an equivalent in mice, because melanopsin immunostaining marks two tiers of dendrites in the IPL, one corresponding to the rodent type already described and a second in the inner IPL (Provencio, I. *et al.*, 2002). This second plexus can be traced to a distinct population of more poorly stained cells in the ganglion cell layer (Castrucci, A. M., Berson, D. M., and Provencio, I., unpublished observations).

Behavioral studies have implicated these cells not only in circadian entrainment and the pupillary light reflex but also in the photic modulation of nocturnal melatonin levels and the acute suppression of activity by light in nocturnal rodents (see Chapter Melanopsin Cells). The functional properties of these cells appear well matched to these functional roles, with remarkably sustained responses to steady illumination that stably encode global light intensity (Berson, D. M. *et al.*, 2002).

The most comprehensive picture of the efferent projections of these cells comes from a mouse line genetically modified to express beta-galactosidase in the axons of melanopsin RGCs (Hattar, S. *et al.*, 2002; 2006). Similar data are available in rat using PACAP immunoreactivity as a marker for axons originating from melanopsin RGCs (Hannibal, J. and Fahrenkrug, J., 2004), though the interpretation of these patterns is complicated by the presence of PACAP immunopositive axons of nonretinal origin. Other experiments, combining retrolabeling with *in situ* hybridization or antimelanopsin immunolabeling, confirm several of the major projections of melanopsin RGCs (Gooley, J. J. *et al.*, 2003; Sollars, P. J. *et al.*, 2003; Hattar, S. *et al.*, 2002; Berson, D. M. *et al.*, 2002; Morin, L. P. *et al.*, 2003; Dacey, D. M. *et al.*, 2005; Hannibal, J. *et al.*, 2002). Individual targets are discussed in the section on retinofugal projections and are also reviewed in Chapters Melanopsin Cells, The Suprachiasmatic Nucleus, and Pupillary Control Pathways. To summarize briefly, two of the most prominent targets are the SCN and the intergeniculate leaflet, a division of the lateral geniculate nucleus (LGN) that has been implicated in circadian regulation. Another major target is the olivary pretectal nucleus, the critical brainstem relay for the pupillary light reflex. Minor axonal targets include the preoptic region, supraoptic nucleus of the hypothalamus, amygdala, and the ventral division of the lateral geniculate nucleus (LGNv). Most of these projections are implicated in reflexive physiological responses to light in such domains as sleep and neuroendocrine function. However, at least sparse projections have also been traced to the superior colliculus and dorsal division of the LGN (LGNd), two structures playing key roles in higher-resolution form vision or visuomotor behaviors (Morin, L. P. *et al.*, 2003; Dacey, D. M. *et al.*, 2005; Hattar, S. *et al.*, 2006).

1.25.3.2 ON Direction-Selective Cells

A second highly conserved cell type for which there is excellent structural, physiological, and behavioral information is the ON direction-selective RGC (ON-DS cell). These large-field monostratified cells (Figure 1) encode the direction of whole-field visual motion (retinal slip) and relay this signal to the accessory optic system (AOS) of the brainstem, which drives optokinetic responses. A synopsis of the close functional interrelationships between ON-DS cells and the optokinetic system is provided below (see Section 1.25.4.4).

The ON-DS cell was originally recognized and described in the rabbit retina, and it remains by far best characterized in this species. The original physiological description was made by Barlow H. B. *et al.* (1964). Oyster C. W. and Barlow H. B. (1967) demonstrated that these cells preferred slow stimulus velocities and were grouped into three subtypes, each with a characteristic preferred direction: superior temporal, inferior temporal, or temporonasal. The morphology of rabbit ON-DS cells is well established. Oyster C. W. *et al.* (1980) made initial morphological observations on presumptive ON-DS cells using retrograde labeling from the AOS. Buhl E. H. and Peichl L. (1986) provided a detailed description of the somadendritic architecture of these cells by making intracellular dye injections into RGCs retrolabeled from the medial terminal nucleus of the AOS. This labeled a single morphological cell type, with a large soma, and a large dendritic field stratifying almost entirely within the ON sublayer of the IPL. Dendrites exhibited moderate branching density and a space-filling structure (Figure 1).

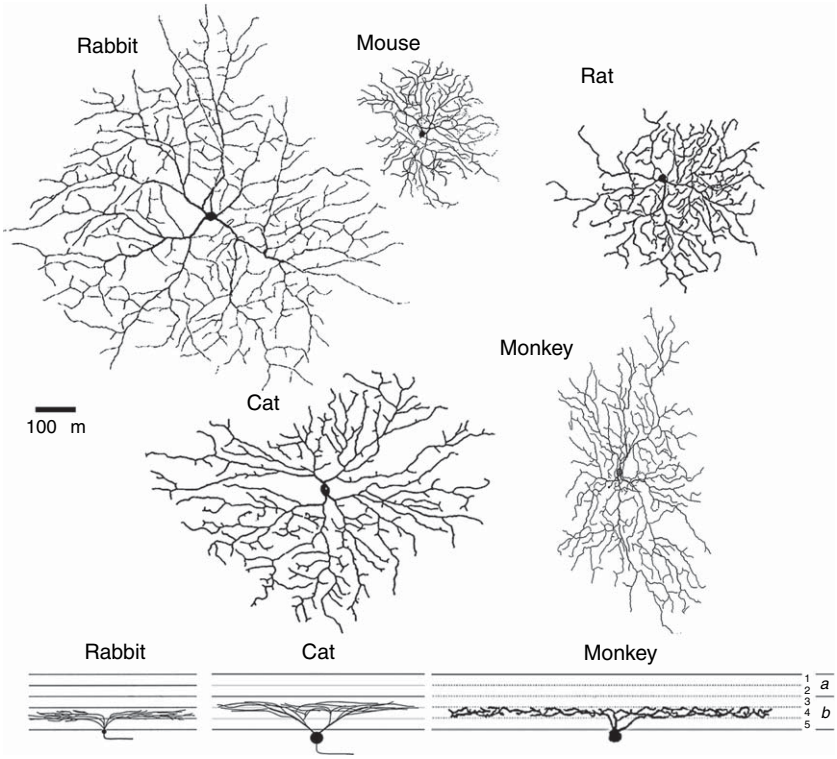

Figure 1 Morphology of known or presumed ON direction-selective (ON-DS) retinal ganglion cells in five mammalian species. Top panels show dendritic profiles as viewed in flatmounts. The rabbit and rat cells were dye-filled after retrograde labeling from the medial terminal nucleus of the accessory optic system. Rabbit RGCs with this morphology are known to be ON-DS cells physiologically (see text), and this was confirmed directly for the mouse cell illustrated. Cells with similar morphology are shown for cat and monkey retina. The contrast of some cells has been adjusted. Scale bar (=100 μm) applies to all of these profiles. Each of these types stratifies near the middle of the ON sublayer of the IPL, as shown below in schematic vertical sections. Panels have been resized and reoriented as needed for ready comparison. (Bottom panel, monkey) Large moderate cell from figure 8 of Yamada, E. S., Bordt, A. S., and Marshak, D. W. 2005. Wide-field ganglion cells in macaque retinas. Vis. Neurosci. 22(4), 383–393. © 2005 Cambridge University Press.

Direct structure–function data confirming the identity of these cells as ON-DS cells was made by Amthor F. R. *et al.* (1989a) and later confirmed by He S. and Masland R. H. (1998) and Ackert J. M. *et al.* (2006). Several other purely morphological studies have elaborated the structural description of these cells, including their costratification and co-fasciculation with the dendrites of ON starburst cholinergic amacrine cells (Famiglietti, E. V., 1992 – ON-DS cells; Rockhill, R. L. *et al.*, 2002 – G10 cells; Dong, W. *et al.*, 2004; see also Yamada, E. S. *et al.*, 2005).

This ganglion cell type appears to be highly conserved in form and function in mammalian retinas, as does its role as the primary source of retinal input to AOS. As summarized in Figure 1, morphological types closely matching the rabbit ON-DS cells in branching

pattern and stratification have been observed in mouse (RG_{C1} of Sun, W. *et al.*, 2002b; 2006), rat (Dann, J. F. and Buhl, E. H., 1987), cat (kappa cell; O'Brien, B. J., *et al.* 2002 and unpublished observations), squirrel (G18; Linberg, K. A. *et al.*, 1996), and primate (recursive monostratified cell of Dacey, D. M., 2004; large moderate cell of Yamada, E. S. *et al.*, 2005). In several of these species, the apparent correspondence of these cell types to the rabbit ON-DS type has been strengthened by demonstrating that they can be labeled by retrograde transport from the AOS (rat: Dann, J. F. and Buhl, E. H., 1987) and by direct demonstration of ON-DS physiology (mouse: Sun, W. *et al.*, 2006). ON-DS cells have been encountered in extracellular surveys of cat ganglion cells (Stone, J. and Fukuda, Y., 1974). RGCs retrolabeled from the cat and monkey AOS, though incompletely characterized, are grossly similar to those in rabbits and rodents (Farmer, S. G. and Rodieck, R. W., 1982; Telkes, I. *et al.*, 2000). The functional properties of cells in the AOS are consistent with their input from ON-DS cells in the cat (Grasse, K. L. *et al.*, 1984), rat (van der Togt, C. *et al.*, 1993), and primate (Mustari, M. J. and Fuchs, A. F., 1989; Hoffmann, K. P. and Distler, C., 1989; see also Telkes, I. *et al.*, 2000).

Few projections outside of the accessory optic system have been documented for ON-DS ganglion cells. ON-DS cells preferring temporonasal motion project to the nucleus of the optic tract, a nucleus of the pretectal region closely linked to the AOS (Pu, M. L. and Amthor, F. R., 1990b; Gamlin, P. D., 2005). There is some evidence for a projection to the superior colliculus and LGNd (see below).

1.25.3.3 Local Edge Detectors

Another RGC type that appears highly conserved in mammalian retinas is a relatively small-field monostratified cell, arborizing near the boundary between the ON and OFF sublayers of the IPL, and having an ON–OFF receptive field center. The type is best characterized in the rabbit where it has been termed the local edge detector (LED), but apparently equivalent types have been described in primates, cats, and rodents.

The type was first described physiologically in rabbits by Levick W. R. (1967). His term "local edge detector" was intended to highlight the preference these cells exhibit for stimuli restricted to their small receptive field center and their poor responsiveness to large spots, full-field stimuli, or extended gratings. This selectivity has been attributed to the presence of a strong silent suppressive surround (Levick, W. R. 1967; van Wyk, M. *et al.*, 2006). Like ON–OFF-DS cells (see below), these cells respond well to both small light or dark spots, but unlike that type they exhibit no directional preference.

The morphology of rabbit local edge detectors was first characterized by Amthor F. R. *et al.* (1989a) on the basis of intracellular recording and dye filling, and has been confirmed by Roska B. *et al.* (2006) and van Wyk M. *et al.* (2006). A comprehensive analysis of this morphological type, which goes by various names, has been provided by Rockhill R. L. *et al.* (2002; G1 cell), Famiglietti E. V. (2005a; class IV, type 1, small tufted (IVst1) cell), and van Wyk M. *et al.* (2006; LED). They have the smallest dendritic field diameters of any rabbit ganglion cells. Their highly branched, tortuous dendrites rarely overlap one another (Figure 2). They form a monostratified arbor lying at or very near the boundary between the ON and OFF sublayers of the IPL, sandwiched between the ON and OFF tiers of the ON–OFF DS cell's dendritic arbor (and thus, by extension, between the inner and outer cholinergic bands) (Roska, B. *et al.*, 2006; van Wyk, M. *et al.*, 2006). In this position, these dendrites presumably collect synaptic inputs from both ON and OFF bipolar cell terminals stratifying near the ON/OFF sublaminar border.

Possible structural or functional equivalents of the rabbit LED have been encountered in a wide array of other mammalian retinas (Figure 2), although correlated structural and functional observations have yet to be made in most species. The picture is further complicated by the presence of multiple functional types with ON–OFF receptive field centers and several morphological types with relatively small, highly branched dendritic fields stratifying in mid-IPL.

Among the likely homologs of the LED type among other mammals, the best characterized is probably the zeta morphological type of cat retina (Berson, D. M. *et al.*, 1998; O'Brien, B. J. *et al.*, 2002). Except for the beta cell, these have the smallest dendritic field diameters of any cat RGCs, and their densely branched dendritic arbor is strikingly similar in form and stratification to the rabbit LED (Figure 2). Structure–function work indicates that this cell is, like the rabbit LED, an ON–OFF phasic type (O'Brien, B., Isayama, T., and Berson, D., unpublished observations). Cat ganglion cells with receptive fields resembling rabbit LEDs have been frequently encountered in physiological studies and have been referred to as ON–OFF phasic cells, and impressed-by-contrast cells as well as LEDs (Cleland, B. G. and Levick, W. R., 1974b; Stone, J. and Fukuda, Y., 1974; Troy *et al.*, 1989). A morphological type resembling the cat zeta cell has been described in the ferret,

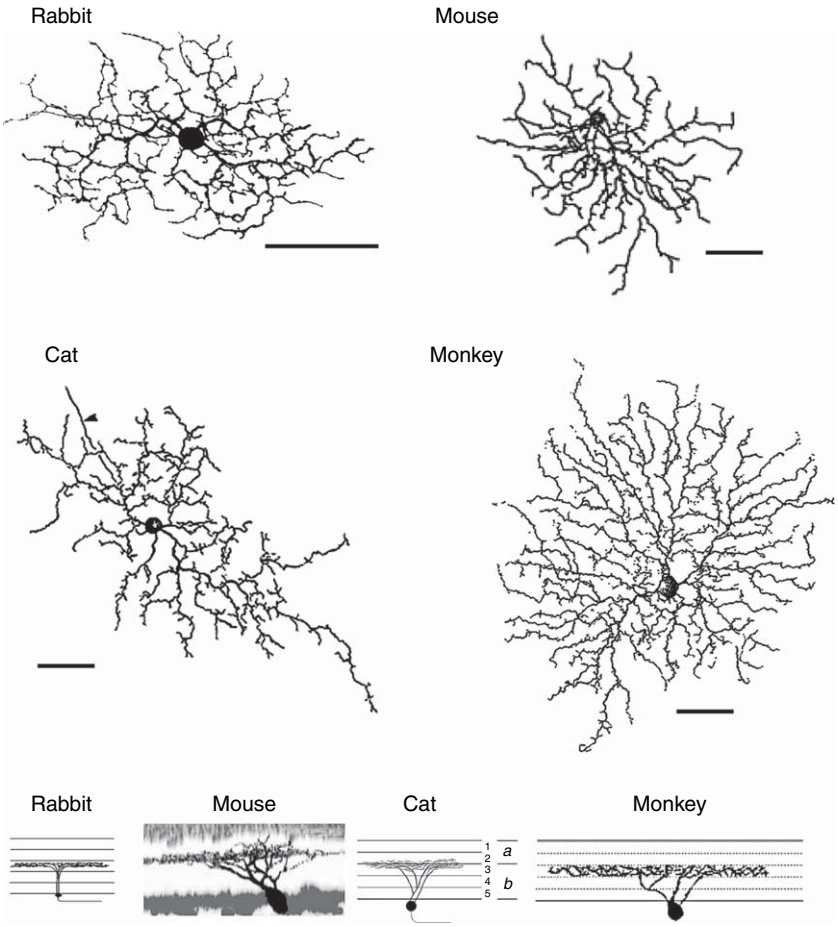

Figure 2 Morphology of ganglion cells of the local edge detector (LED) type in four mammalian retinas. Top panels show dendritic profiles as viewed in flatmounts. The contrast of some cells has been adjusted (and inverted for the rabbit cell) to promote comparisons. Each of these types stratifies near the boundary between the ON and OFF sublayers of the IPL, as shown below in digitally reconstructed or schematic vertical sections. Panels have been resized and reoriented as needed to facilitate comparison. Scale bars = 50 μm. The rabbit LED cell is taken from figure 2A of van Wyk, M., Taylor, W. R., and Vaney, D. I. 2006. Local edge detectors: a substrate for fine spatial vision at low temporal frequencies in rabbit retina. J. Neurosci. 26(51), 13250–13263. The cat RGC is a zeta cell, from figure 1G of Berson, D. another carnivore (tight group of Wingate, R. J. *et al.*, 1992; see Berson, D. M. *et al.*, 1998 for details).

A strikingly similar monostratified type has been observed in primate retina by Rodieck R. W. and Watanabe M. (1993; their maze cell), although its level of stratification was not specified. The broad thorny cell illustrated by Dacey D. M. *et al.* (2003) appears to represent the same type and Dacey D. M.

(2004) reports preliminary evidence that this cell has a transient ON–OFF response to center stimulation. Yamada, E. S. *et al.* (2005) describe a cell type which they term narrow thorny and equate with the rabbit LED. This cell has an appropriate branching pattern and stratifies in the appropriate sublayer (between the ChAT bands). It should be noted, however, that they do not equate their cell with the maze cell of Rodieck R. W. and Watanabe M. (1993). Although the dendritic fields of all of these cell types are substantially larger than those of the midget and parasol cells, they nonetheless have among the smallest fields of any of the many RGCs that are neither midget nor parasol. ON–OFF phasic ganglion cells have been recorded extracellularly in macaque retina by Schiller P. H. and Malpeli J. G. (1977) and de Monasterio F. M. (1978).

In mice, several types of RGCs have small, highly branched dendritic fields and stratification near the interface between the ON and OFF sublayers of the IPL. These include the B2, B4, C4, and C5 types of Sun W. *et al.* (2002b), the M1 and M2 types of Coombs J. *et al.* (2006), cluster 1 cells of Kong J. H. *et al.* (2005), and clusters 1 and 2 of Badea T. C. and Nathans J. (2004). Similar types have been encountered in rat retina (RGB class of Huxlin, K. R. and Goodchild, A. K., 1997; B2 and perhaps B4 types of Sun, W. *et al.*, 2002a) and ground squirrels (G9 cells of Linberg, K. A. *et al.*, 1996). Some of these types, with denser, more highly overlapping dendritic profiles, may actually correspond less well to the rabbit LED than to the type 3 bistratified ganglion cell described in mouse by Schubert T. *et al.* (2005). This small-field type, like the cat theta cell (Isayama, T. *et al.*, 2000), to which it may be homologous, has such a densely branched dendritic arbor that its bistratification is difficult to discern on casual inspection. A compelling case for equivalence between any of these types and the LED is difficult because the differentiation among types is not as obvious in rodents as in the retinas of monkey, cat, or rabbit, and none of these studies used immunostaining of the ChAT plexuses or other fiducial markers for stratification. Nor is there any structure–function work on these types that would permit one to draw a equivalence based on physiological features. Nonetheless, it seems quite likely that cells analogous to the LED are present in rodent retina.

With respect to central projections, there is strong evidence for substantial contributions from this type to the retinocollicular projection, and conflicting evidence on their possible contribution to the retinogeniculate pathway. These outputs are considered more fully in Section 1.25.4.

1.25.3.4 ON–OFF Direction-Selective Cells

One of the best characterized types of RGC in any mammalian retina is a rabbit ganglion cell with an ON–OFF receptive field center and selectivity for the direction of stimulus motion. This ON–OFF DS cell, which has been definitively linked to a bistratified morphological type, is the focus in Chapter Direction-Selective Cells. The reader is referred to that chapter for information about the structure and function of this type and about current understanding of the synaptic basis of its directional preference.

Barlow H. B. and Hill R. M. (1963) provided the first functional description of these cells. Amthor F. R. *et al.* (1984; 1989a) used intracellular recording and dye filling to correlate this functional type with the type I bistratified morphological type, a finding that has been repeatedly confirmed (see Chapter Direction-Selective Cells). These cells have both somas and dendritic fields of intermediate size. A key structural feature is a clearly bistratified dendritic architecture, with an inner arbor costratifying with the cholinergic band in the ON sublayer of the IPL and the outer arbor costratifying with OFF cholinergic plexus (Famiglietti, E. V., 1992a).

Although nearly all the work on this cell type has been conducted in the rabbit retina, there is emerging evidence for the presence of homologous types in a variety of mammalian orders (Figure 3). In mice, an apparently homologous morphological type (RG_{D2} cell, Sun, W. *et al.*, 2002b; type 2 bistratified cell, Schubert, T. *et al.*, 2005) has recently been confirmed to be an ON–OFF DS type physiologically (Weng, S. *et al.*, 2005). In cat retina, ON–OFF DS cells have been encountered in extracellular recording surveys (Cleland, B. G. and Levick, W. R., 1974a; Stone, J. and Fukuda, Y., 1974), a bistratified morphological type with structural features strikingly similar to those of the rabbit type has been identified (Famiglietti, E. V., 1987, class IV, type 4; O'Brien, B. J. *et al.*, 2002, iota cell), and a preliminary structure/function correlation has made by recording and dye injection (O'Brien, B. J., Isayama, T., and Berson, D. M., unpublished observations). Similar morphological types have been reported in rat (RG_{D2} cell, Sun, W. *et al.*, 2002a), ground squirrel (G11; Linberg, K. A. *et al.*, 1996), and macaque (recursive monostratified cell of Dacey, D. M., 2004; multitufted cell of Yamada, E. S. *et al.*, 2005).

Remarkably little has been done to characterize the patterns of central projection of this cell type in any mammalian retina. However, there is at least

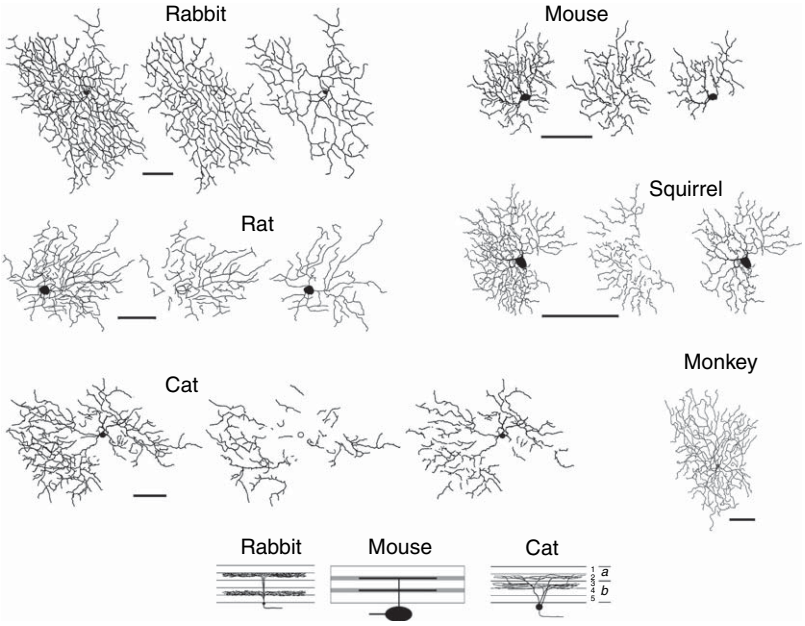

Figure 3 Morphology of known or presumed ON–OFF direction-selective (ON–OFF DS) retinal ganglion cells in six mammalian species. Top panels show dendritic profiles as viewed in flatmounts. Except for the monkey cell (lower right), each profile is shown three times. The leftmost is a representation of the entire profile, the middle shows only that part of the profile occupying the OFF sublayer of the IPL, and the right shows only the inner, ON arbor. The rabbit, mouse, and cat cells of this type have been physiologically confirmed to be ON–OFF DS cells physiologically (see text). The bistratified architecture of each of these types is shown below in schematic vertical sections. Shaded bands in mouse stratification drawing correspond to cholinergic plexuses. ON–OFF DS cell dendrites costratify with these ChAT bands in all species examined, though their positions relative to the boundaries of the IPL vary slightly among species (Famiglietti, E. V. 1987). Panels have been slightly edited to promote comparisons. Scale bars = 100 μm. (Top panel, rabbit) Derived from figure 12 of Vaney, D. I. 1994. circumstantial evidence for contributions to both the retinogeniculate and retinocollicular projections in a variety of species (see Section 1.25.4).

1.25.3.5 Alpha Cells

Alpha cells were originally described in cat retina by Boycott B. B. and Wässle H. (1974), where they are easily recognized by their extremely large cell bodies, thick axons, and large radiate dendritic fields (Figure 4). Presumed homologs of this cell type have been proposed in a larger number of mammalian species than for any other RGC type. This apparent consistency is deceptive, however, as several varieties of alpha-like cells have been recognized in rodent, rabbit, and primate retinas and there has been

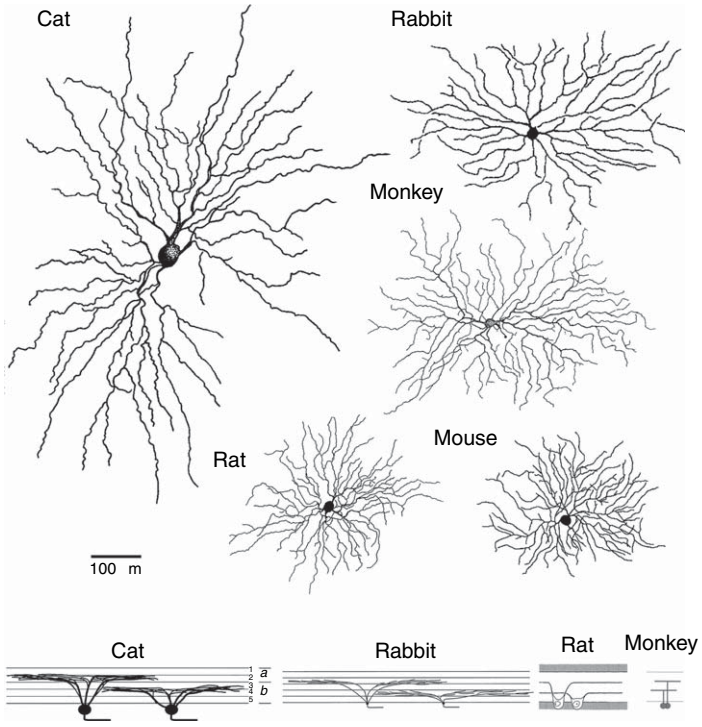

Figure 4 Morphology of alpha-like ganglion cells in five mammalian species. Top panels show dendritic profiles as viewed in flatmounts. Each of these types occurs as a paramorphic pair, with one subtype stratifying in the middle of the ON sublayer and the other in the middle of the OFF sublayer, as shown below in schematic vertical sections. Some panels have been modified slightly to promote comparison. Scale bars = 100 μm. (Top panel, rabbit) Alpha cell from figure 12 of Peichl, L., Buhl, E. H., and Boycott, B. B. 1987a. considerable controversy about which of these should be considered true homologs of the cat alpha cell.

Cat alpha cells comprise a paramorphic pair of subtypes, one ON and one OFF. Each subtype forms a regular mosaic that efficiently tiles the retina (Wässle, H. and Boycott, B. B., 1991; Chapter Mosaics, Tiling and Coverage by Retinal Neurons) and is narrowly monostratified near the middle of its respective sublamina, at approximately the same depth as the cholinergic plexuses (Vardi, N. *et al.*, 1989). Dendrites are relatively stout, branch at moderate density with acute branch angles, and overlap one another minimally. In their original report, Boycott B. B. and Wässle H. suggested a possible correspondence between alpha cells and Y cells, a physiological type of cat RGC distinguished by a

brisk, transient light response, fast axonal conduction velocity, and nonlinear spatial summation. This was quickly confirmed (Cleland, B. G. *et al*, 1975; Peichl, L. and Wässle, H., 1981; Saito, H. A., 1983; Fukuda, Y. *et al*., 1984; Stanford, L. R. and Sherman, S. M., 1984).

Paramorphically paired cell types with morphology resembling that of the cat alpha cells have been documented in marsupials, rodents, bats, carnivores, lagomorphs, ungulates, and primates (Perry, V. H., 1979; Vitek, D. J. *et al*., 1985; Peichl, L. *et al*., 1987a; Peichl, L., 1989; 1992; Dann, J. F. and Buhl, E. H., 1990; Wingate, R. J. *et al*., 1992; Huxlin, K. R. and Goodchild, A. K., 1997; Sun, W. *et al*., 2002a; 2002b). Figure 4 shows examples of such proposed homologs. Though nomenclature for these types has been variable (e.g., type I cells of Perry, V. H., 1979; RG_{A2} cells of Huxlin, K. R. and Goodchild, A. K., 1997 and Sun, W. *et al*., 2002a; 2002b), some have specifically referred to these morphological types as alpha cells (e.g., Perry, V. H. and Cowey, A., 1981; Peichl, L. *et al*., 1987a; 1987b; Peichl, L., 1989; 1991; 1992; Zhang, J. *et al*., 2005; Pang, J. J. *et al*., 2003). Structure–function data are lacking for many of these species, but at least some of these alpha-like forms do exhibit physiological properties broadly consistent with those of cat alpha (Y) cells (Amthor, F. R. *et al*., 1989b; Demb, J. B. *et al*., 1999; Pang, J. J. *et al*., 2003).

However, uncertainty about the implied homology with cat alpha cells has grown over the years, particularly in the better-studied species. For example, in the rat retina, Peichl L. (1989) initially described a single paramorphic pair of types with alpha-like morphology, but two subsequent studies suggest that the cells illustrated by Peichl comprise three types (Huxlin, K. R. and Goodchild, A. K., 1997; Sun, W. *et al*., 2002a). Two of these types form a paramorphic pair, termed RGA_2, that is arguably homologous to cat alpha cells. The third is an unpaired ON type, termed RGA1, characterized by a slightly larger, sparser dendritic profile that stratifies just beneath (i.e., vitread to) the presumed ON alpha homolog. A similar interpretation has been reported by at least one group in the mouse retina (Sun, W. *et al*., 2002b) but there appears to be no consensus on this point. For example, Coombs J. *et al*. (2006) consider their cluster M10 cells to be the probable mouse equivalent of alpha cells, but indicate that this type stratifies only in the ON sublayer and also equate them with the RG_{A1} cell of Sun W. *et al*. (2002b). Kong J. H. *et al*. (2005) suggest that mouse RGCs belonging to their clusters 10 and 11 comprise a paramorphic pair corresponding to the alpha cells, but also equate their cluster 11 with the RGA1 cells of Sun W. *et al*. (2002b) and offer their cluster 8 as an alternative candidate for the ON alpha homolog. To further complicate matters, Pang J. J. *et al*. (2003) found that mouse RGCs with large somas and alpha-like dendritic arbors consist of three functional types, two of which are OFF-center.

The uncertainty seems at least as great in the rabbit retina, as comprehensively reviewed by Famiglietti E. V. (2004) and Zhang J. *et al*. (2005). Several studies report a single paramorphic pair of alpha-like types (Peichl, L. *et al*., 1987a; Rockhill, R. L. *et al*., 2002; Zhang, J. *et al*., 2005), each of which exhibits a regular spacing of somata like those of other well-defined types (Peichl, L. *et al*., 1987a). However, Famiglietti recognizes no fewer than seven distinct morphological types among his type I and II classes, which resemble, more or less strongly, the alpha type, having relatively large somas and large, radiate dendritic fields. His type Ia2 and Ib2 form a paramorphic pair that appears to correspond best to the alpha cells described by Zhang J. *et al*. (2005). Interestingly, these two types apparently do not costratify with the ChAT bands as they do in the cat (Vardi, N. *et al*., 1989), arborizing instead just beneath those bands (Famiglietti, E. V., 2004; Zhang, J. *et al*., 2005). This may reflect differences among studies in the precision of laminar assignments, a real species difference in stratification of otherwise homologous types, or real differences that argue against true homology. Electrophysiological studies of rabbit retina have identified various types of brisk, large-field units likely to represent the functional equivalents of these alpha-like RGCs (Levick, W. R., 1967; Caldwell, J. H. and Daw, N. W., 1978; Vaney, D. I. *et al*., 1981a). The possible correspondences between these functional types and various alpha-like morphological types have been systematically evaluated by Famiglietti E. V. (2004). Structure–function studies show that at least some rabbit alpha-like cells have relatively transient, spatially nonlinear response properties resembling those of cat Y cells (Amthor, F. R. *et al*., 1989b; Jensen, R. J., 1991; Roska, B. *et al*., 2006).

The question of whether the primate retina contains a homolog of the alpha cell type remains controversial. The morphological cell type termed parasol by Polyak S. L. (1941) and referred to by others as Pα, A, or M (magnocellular-projecting) cells, has often been proposed as such a homolog

(e.g., Leventhal, A. G. *et al.*, 1981; Perry, V. H. and Cowey, A., 1981; Peichl, L., 1991). In favor of this proposed correspondence is the relatively large soma size of this type, its preferential staining by neurofibrillar methods, general features of its branching pattern and its projection to the LGNd, and its tracer coupling pattern (for details, see Peichl, L., 1991; Dacey, D. M. and Brace, S., 1992). Physiologically, these cells, like cat Y cells, exhibit transient light responses and high contrast sensitivity. On the other hand, parasol cells represent a larger fraction of the ganglion cell population than the do the alpha cells of cats or other species (~10% as compared to 1–4%). Also, though their dendritic fields are certainly larger than those of midget cells, they have smaller dendritic fields than most remaining ganglion cell types, whereas in most species alpha cells are among the largest-field types. Furthermore, many M (parasol) cells exhibit linear spatial summation, whereas Y (alpha) cells are nonlinear (Shapley, R. and Perry, V. H., 1986). Finally, in marked contrast to cat alpha cells, primate parasol cells contribute very little to the retinotectal projection (Leventhal, A. G. *et al.*, 1981; Rodieck, R. W. and Watanabe, M., 1993; see also Schiller, P. H. and Malpeli, J. G., 1977).

Recent studies have identified what may prove to be a better primate homolog of the alpha cell. Dacey D. M. (2004) describes a cell type he terms "smooth monostratified" (see Figure 4) which has the relatively coarse, smooth dendrites and radiate branching structure characteristic of alpha cells in other species. Both the cell body and the dendritic field are substantially larger than that of parasol cells and thus more reminiscent of alpha cells. Yamada E. S. *et al.* (2005) describe a similar type which they term "large radiate." They note that the dendrites of these cells minimally overlap one another and that their axons are relatively thick, again paralleling feature of cat alpha cells. Both groups agree that like alpha cells, this type comprises a paramorphic pair (Dacey, D. M., 2004; Yamada, E. S. *et al.*, 2005). One subtype costratifies with the dendrites of the ON starburst amacrines, and the other with the OFF starbursts (i.e., in register with the ChAT bands; Yamada, E. S. *et al.*, 2005). Recent evidence suggests that these cells share with cat alpha cells the same relative abundance (3% of all RGCs), nonlinear spatial summation, and prominent projections to both the LGN and superior colliculus (Dacey, D. M., 2004; Crook, J. D. *et al.*, 2007; and Dacey, D. M. personal communication). Thus, on many grounds, this type seems to match the alpha type much closely than does the parasol cell.

1.25.3.6 Beta Cells

This morphological type was first characterized, along with alpha cells, by Boycott B. B. and Wässle H. (1974). They suggested beta cells might be the morphological equivalent of the X cell, a brisk sustained physiological type exhibiting linear spatial summation (Stone, J., 1983). This was confirmed in structure–function work (Fukuda, Y. *et al.*, 1984; Saito, H. A., 1983; Stanford, L. R. and Sherman, S. M., 1984). The beta cells have the smallest receptive fields of all cat RGCs and project heavily to the LGNd. There is thus little doubt that they mediate the highest acuity vision of which cats are capable. Beta (X) cells apparently also innervate the pretectal region but lack any projection to the superior colliculus (Stone, J., 1983; Tamamaki, N. *et al.*, 1995).

Homologs of the beta cell are readily recognizable in other carnivores (ferret: Vitek, D. J. *et al.*, 1985; Wingate, R. J. *et al.*, 1992; dog and wolf: Peichl, L., 1992) and very similar morphological cell types have been documented in species belonging to other mammalian orders, including the flying fox (a variety of fruit bat; Dann, J. F. and Buhl, E. H., 1990) and the opossum (Wilson, P. D. and Condo, G. J., 1985; Moraes, A. M. *et al.*, 2000). On the other hand, it has been much more difficult to establish homologous types in some of the best-studied mammalian retinas. In primates, a RGC type variously termed midget, Pβ, B, or P (parvocellular projecting) has often been considered to be the likely primate equivalent of the beta cell, but there is no consensus on this point (for review, see Wässle, H. and Boycott, B. B., 1981; Shapley, R. and Perry, V. H., 1986; Peichl, L., 1991; Rodieck, R. W., 1988; 1998). Rodieck has noted the close morphological similarity of primate parasol and cat beta cells. Silveira L. C. *et al.* (1994) suggest that after normalizing for local density of each type, cat alpha and beta cells and primate parasol cells all strongly resemble one another, whereas midget cells stand alone. Shapley R. and Perry V. H. (1986) have pointed out that the primate magnocellular layers, to which parasol cells make the dominant input, contain many cells with X-like linear spatial summation and recordings recently made from identified parasol cells suggest that they exhibit far more linearity of spatial summation than previously recognized (Dacey, D. M., personal communication). A plausible alternative view, then, is that the parasol cell is the primate homolog of the beta cell, while the midget cells constitute a type unique to primates.

The situation is even less clear in rabbits and rodents. Neither have a clear morphological counterpart of the beta cell (Peichl, L. *et al.*, 1987a; Rockhill, R. L. *et al.*, 2002; Famiglietti, E. V., 2004; Sun, W. *et al.*, 2002a; 2002b; Kong, J. H. *et al.*, 2005; Coombs, J. *et al.*, 2006; Badea, T. C. and Nathans, J., 2004), though possible equivalents have been suggested on anatomical grounds (Fukuda, Y., 1977; Thanos, S., 1988; Rivera, N. and Lugo, N., 1998). In mouse retina, there is no physiological type that is distinguishable on the basis of its X-like linearity of spatial summation (Carcieri, S. M. *et al.*, 2003). In rabbits, receptive fields resembling those of cat X cells, with brisk sustained responses to light steps and linear spatial summation, have been encountered (X cells, Caldwell, J. H. and Daw, N. W., 1978; brisk sustained, Vaney, D. I. *et al.*, 1981a; brisk-sustained linear, Amthor, F. R. *et al.*, 1989b), but the distinction from rabbit Y-like cells is more difficult than in cat (see Famiglietti, E. V., 2004 for details). Structure–function data from Amthor F. R. *et al.* (1989b) and Roska B. *et al.* (2006) have linked this functional type mainly to a cell type with highly branched dendritic field of intermediate size. This morphological type, termed "beta" by Roska B. *et al.* (2006), appears to correspond to the G4 cell of Rockhill R. L. *et al.* (2002) and certain cells within class III of Famiglietti E. V. (2004). However, the equivalence of this type to cat beta cells on morphological grounds is far from clear, and the light responses of these cells appear far more transient than those of cat X (beta) cells. Famiglietti E. V. (2004) has argued that much larger-field cells within his class II may be the morphological equivalent of the brisk-sustained linear physiological type.

1.25.4 Retinofugal Projections and Their Origin in Specific Ganglion Cell Types

Retinofugal projections have been extensively explored in a large number of mammalian brains for many decades. The subnuclear organization of retinorecipient nuclei and the classification schemes for RGCs vary considerably from one species to the next. The literature on parallel retinofugal channels is thus too vast to be comprehensively covered in this chapter. The goal here is merely to survey the range of retinal targets, to summarize the main established functional roles of these nuclei, and to provide a brief synopsis of what is known about the types of RGCs that innervate them, with particular emphasis on the conserved types discussed above. Several of the major targets are the subject of separate chapters in this volume and their consideration here will be correspondingly brief.

1.25.4.1 Methods for Linking Retinofugal Projections to Retinal Ganglion Cell Types

The most complete surveys of retinofugal projections come from axon transport tracing experiments using the most sensitive available tracers, of which the most popular is the B subunit of cholera toxin. Such surveys are available for a wide variety of mammalian brains, including mouse (Godement, P. *et al.*, 1984; Miura, M. *et al.*, 1997; Hattar, S. *et al.*, 2006); rat (Levine, J. D. *et al.*, 1991; Hannibal, J. and Fahrenkrug, J., 2004); blind mole rat (Cooper, H. M. *et al.*, 1993); squirrel (Agarwala, S. *et al.*, 1989; Major, D. E. *et al.*, 2003); hamster (Pickard, G. E. and Silverman, A. J., 1981; Morin, L. P. and Blanchard, J. H., 1997; Ling, C. *et al.*, 1998; Johnson, R. F. *et al.*, 1988; Mikkelsen, J. D., 1992; Pickard, G. E. and Silverman, A. J., 1991; Reuss, S. and Decker, K., 1997; Youngstrom, T. G. *et al.*, 1991); cat (Matteau, I. *et al.*, 2003); and primates (Cooper, H. M. *et al.*, 1990; Mick, G. *et al.*, 1993; Costa, M. S. *et al.*, 1999; Abizaid, A. *et al.*, 2004). An additional source of information concerning retinal projections in mice comes from genetically modified strains in which specific subsets of RGCs have been induced to express marker proteins that are axonally distributed (Quina, L. A. *et al.*, 2005; Hattar, S. *et al.*, 2006).

Information about which specific morphological types of RGCs innervate these targets comes primarily from studies using retrograde transport. Typically this tracing method yields granular labeling within the soma and primary dendrites of RGCs. This can be used to obtain evidence about the size of the afferent RGCs, about their laterality of projection and topographic distribution, but only crude information about their dendritic structure. Beginning in the 1980s, methods were introduced for labeling cells by retrograde transport of fluorescent tracers, and for targeting the labeled cells for intracellular staining in fixed or living tissue. This innovation made it possible to reveal the full dendritic architecture of RGCs with known central projections (e.g., Buhl, E. H. and Peichl, L., 1986; Dann, J. F. and Buhl, E. H., 1987; Pu, M. L. and Amthor, F. R., 1990a; 1990b; Wingate, R. J. *et al.*, 1992; Rodieck, R. W. and Watanabe, M., 1993; Pu,

M. L. *et al.*, 1994). In a particularly powerful modification of this method, light has been used to induce the release of a retrograde fluorescent tracer from endocytotic vesicles in the soma into the cytosol. The dye diffuses freely within the cell, yielding smooth intracellular filling similar to that produced by intracellular dye injection (Dacey, D. M. *et al.*, 2003). In a few studies, inferences about the heterogeneity of RGCs innervating a particular central target have been made from a close examination of bulk-filled retinal afferents (e.g., Sachs, G. M. and Schneider, G. E., 1984). However, except in the case of intracellular recording from relatively large axons (e.g., Bowling, D. B. and Michael, C. R., 1980; Tamamaki, N. *et al.*, 1995), it has been difficult to link these arbor types to specific RGC classes.

For identifying physiological types of RGCs providing input to specific central nuclei, antidromic activation has been until very recently the method of choice. In some cases, orthodromic activation of postsynaptic targets by shocks to the optic pathway can be used to assess the conduction velocity of retinal afferents and thereby to draw inferences about the functional types of RGCs providing input. In a few targets, such as the LGNd and accessory optic system, where individual cells appear to receive inputs mainly from single RGC types, it has been possible to infer the RGC input population from postsynaptic visual response properties. This approach is impractical for many target nuclei in which postsynaptic properties can be significantly transformed by convergent input from multiple RGC types, extraretinal visual inputs and local circuits. By far the most powerful methods for linking specific functional types to outputs use retrograde transport of fluorescent tracers to label the afferent RGCs, which can then be targeted for *in vitro* recording. Though technically challenging, this approach has the added advantage of permitting intracellular dye injection or photofilling of recorded cells and thus a triple correlation between somadendritic structure, receptive field type, and central projection.

1.25.4.2 Lateral Geniculate Complex and Dorsal Thalamus

The lateral geniculate complex is the most prominent target of retinal projections in mammals. It consists of several distinct components. Of these, the best known and most thoroughly studied is the dorsal division (LGNd). The LGNd serves as the thalamic relay nucleus of the visual system routing retinal signals to the visual cortex. It thus plays an essential role in the cortical analysis of visual form and motion and in conscious visual perception. Chapter The Visual Thalamus provides an extensive review of the functional organization of the retinogeniculate projection. Of greatest relevance in the present context is that multiple ganglion cell types innervate the nucleus, that each type apparently terminates on a distinct set of LGNd neurons, and that these neurons are often segregated in separate sublaminae or subnuclei of the LGNd. In general, the available evidence suggests that many RGC types in a given species innervate the LGNd, but that not all do (e.g., Illing, R. B. and Wässle, H., 1981; Leventhal, A. G. *et al.*, 1981; 1985; Stone, J., 1983; Perry, V. H. and Cowey, A., 1984; Pu, M. L. and Amthor, F. R., 1990a; Wingate, R. J. *et al.*, 1995; Berson, D. M. *et al.*, 1998; 1999; Isayama, T. *et al.*, 2000; Dacey, D. M. *et al.*, 2003, Dacey, D. M., 2004). However, it is difficult to demonstrate definitively that an RGC type lacks a projection to the LGNd. This is because the retrograde tracers that are typically used to address such questions can label fibers passing through an injection site as well as axons terminating there. Some laminae of the LGNd lie so close to the optic tract that it is difficult to make tracer deposits there without involving passing retinofugal fibers.

As reviewed in detail in Chapter The Visual Thalamus, the most complete picture of the multiple functional components within the retinogeniculate pathway comes from work in primates and cats. In primates, the dominant retinal inputs to the parvocellular layers of the primate LGNd derives from midget (P) cells, that to the magnocellular layers comes mainly from the parasol (M) cells, while input to the koniocellular layers comes from a variety of widefield RGC types clearly distinct from midget and parasol cells (see Chapter The Visual Thalamus; Leventhal, A. G. *et al.*, 1981; Perry, V. H. *et al.*, 1984; Irvin, G. E. *et al.*, 1986; Casagrande, V. A., 1994; Dacey, D. M., 1994; 2004; White, A. J. *et al.*, 1998; Dacey, D. M. *et al.*, 2003; Hendry, S. H. and Reid, R. C., 2000; Shapley, R. and Perry, V. H., 1986; Calkins, D. J. *et al.*, 2005; Callaway, E. M., 2005). In cat, the large-celled A layers of the LGNd receive input exclusively from beta (X) and alpha (Y) cells, while the small-celled C layers and the medial interlaminar nucleus receive inputs mainly from alpha cells and from a variety of RGCs with small cell bodies and functional properties distinct from X and Y cells, which are sometimes grouped under the physiological designation W cells or the

morphological class gamma cells (Cleland, B. G. *et al.*, 1976; Wilson, P. D. *et al.*, 1976; Bowling, D. B. and Michael, C. R., 1980; Itoh, K. *et al.*, 1981; Sur, M. and Sherman, S. M., 1982; Stone, J., 1983; Sur, M. *et al.*, 1987; Berson, D. M. *et al.*, 1999; Isayama, T. *et al.*, 2000). A similar organization appears to apply to the ferret LGNd (Vitek, D. J. *et al.*, 1985; Wingate, R. J. *et al.*, 1992).

In mammals with poorly developed geniculate lamination, such as rodents and rabbits, the segregation among retinogeniculate channels is less obvious, but there is nonetheless diversity of the retinogeniculate pathway which is maintained to some degree in the properties of geniculate neurons (Hale, P. T. *et al.*, 1979; Dreher, B. *et al.*, 1985; Martin, P. R., 1986; Pu, M. L. and Amthor, F. R., 1990a). Latent laminar organization has been suggested in rodent and rabbit studies in which afferents from subsets of RGCs have been visualized by classical anatomical methods (Martin, P. R., 1986; Reese, B. E., 1988) or by molecular means (Brecha, N. *et al.*, 1987; Quina, L. A. *et al.*, 2005; Hattar, S. *et al.*, 2006).

Several of the highly conserved RGC types reviewed in the first part of this chapter appear to provide input to the LGNd. One of these is the ON–OFF DS type. LGNd relay cells with physiology closely matching that of ON–OFF DS ganglion cells have been encountered in various mammalian species (rabbit: Levick, W. R. *et al.*, 1969; cat: Cleland, B. G. *et al.*, 1976; Wilson, P. D. *et al.*, 1976; primate: Norton, T. T. and Casagrande, V. A., 1982; Irvin, G. E. *et al.*, 1986; Casagrande, V. A., 1994) and RGCs with bistratified morphology matching that of ON–OFF DS cells have been retrolabeled from the geniculate in rabbits (Pu, M. L. and Amthor, F. R., 1990a). There is some morphological evidence that the ON-center type of DS cells may also innervate the rabbit LGN (Pu, M. L. and Amthor, F. R., 1990a; Dacey, D. M., 2004). Alpha or alpha-like cells innervate the LGNd in cats (Illing, R. B. and Wässle, H., 1981; Stone, J., 1983; Leventhal, A. G. *et al.*, 1985), ferrets (Vitek, D. J. *et al.*, 1985; Wingate, R. J. *et al.*, 1992), rabbits (Pu, M. L. and Amthor, F. R., 1990a), and rats (Dreher, B. *et al.*, 1985). In primates, the LGNd receives input not only from the parasol cells, which have traditionally been considered homologous to the alpha cell, but also from the newly discovered alpha-like (smooth monostratified) cell which is a more likely homolog (Dacey, D. M., 2004; Crook, J. D. *et al.*, 2007). Beta (X) cells provide a major input to the LGNd in carnivores (e.g., Stone, J., 1983; Vitek, D. J. *et al.*, 1985; Wingate, R. J. *et al.*, 1992) and both midget and parasol cells of primates, which some have suggested as homologs of beta cells, likewise innervate the LGNd.

There is conflicting evidence on the question of whether the LED ganglion cell type innervates the LGNd. Several extensive morphological surveys of LGN-projecting RGCs in various mammalian species encountered few if any of this ganglion cell type (rabbit: Pu, M. L. and Amthor, F. R., 1990a; ferret: Wingate, R. J. *et al.*, 1992; macaque: Rodieck, R. W. and Watanabe, M., 1993; cat: Berson, D. M. *et al.*, 1998). However, it would be premature to exclude a projection to the geniculate, especially to the koniocellular or related layers, some of which are difficult to study with retrograde labeling methods due to the proximity of the optic tract. In macaque, the possibly homologous broad thorny type has been retrolabeled from the LGN (Dacey, D. M. *et al.*, 2003; Dacey, D. M., 2004), and de Monasterio F. M. (1978) was able to antidromically activate a few LED-like RGCs from the geniculate. LGN relay cells tend to closely resemble their RGC inputs in receptive-field organization, and geniculate cells with LED-like receptive fields have been encountered in many mammalian species (cat: Cleland, B. G. *et al.*, 1976; Wilson, P. D. *et al.*, 1976; bush baby: Norton, T. T. and Casagrande, V. A., 1982, Irvin, G. E. *et al.*, 1986; tree shrew: Holdefer, R. N. and Norton, T. T., 1995). Melanopsin-expressing RGCs have at most a very sparse and localized input to the LGNd in rodents (Hattar, S. *et al.*, 2002; 2006; Hannibal, J. and Fahrenkrug, J., 2004) but appear to have a more substantial projection to the primate LGNd (Dacey, D. M. *et al.*, 2005).

There are two other components of the geniculate complex that lack direct projections to the cortex and probably play little role in conscious vision. The first is the ventral division of the (LGNv), known in primates as the pregeniculate nucleus. This is a diencephalic region derived, like the zona incerta and thalamic reticular nucleus, from the embryonic ventral thalamus. The connectivity, neurochemistry, and physiological properties of the LGNv have been comprehensively reviewed by Harrington M. E. (1997). The nucleus is heavily interconnected with retinorecipient brain regions and receives input also from brainstem regions related to vestibular and oculomotor function. Visual receptive fields are large and light responses are typically dominated by sustained ON components. Relatively little is known about the ganglion cell types innervating this nucleus. In the cat, RGCs with small somas

which are clearly distinct from alpha and beta cells provide the dominant input (Leventhal, A. G. *et al.*, 1985). In rodents, melanopsin-expressing RGCs provide modest input to this nucleus (Hattar, S. *et al.*, 2002; 2006; Hannibal, J. and Fahrenkrug, J., 2004).

A second accessory component of the LGN complex is the intergeniculate leaflet (IGL), a thin sheet of neurons sandwiched between the LGNd and LGNv in rodents. The IGL is intimately interconnected with the SCN and is thought to contribute to mechanisms synchronizing circadian rhythms to environmental stimuli, both photic and nonphotic (Moore, R. Y. and Card, J. P., 1994; Harrington, M. E., 1997; Morin, L. P. and Blanchard, J. H., 1998). Mammals other than rodents lack an obvious IGL, although possibly homologous regions within primate pregeniculate nucleus and cat LGNv have been proposed based on patterns of connections and neurochemistry (Moore, R. Y., 1993; Pu, M. and Pickard, G. E., 1996; but see Chevassus-au-Louis, N. and Cooper, H. M., 1998). Many IGL neurons exhibit sustained ON responses that code light intensity (Harrington, M. E., 1997). This is in keeping with the observation that melanopsin-expressing RGCs, some with bifurcating projections to the SCN, provide most of the retinal input to this region (Pickard, G. E., 1985; Morin, L. P. *et al.*, 2003; Hattar, S. *et al.*, 2006).

Relatively sparse retinal projections have been traced to a number of regions of the dorsal thalamus other than the LGN complex. The most prominent of these lies just outside the LGNd in the pulvinar or lateral posterior nuclei (e.g., Berman, N. and Jones, E. G., 1977; Mizuno, N. *et al.*, 1982; Leventhal, A. G. *et al.*, 1980; Somogyi, G. *et al.*, 1981; Ling, C. *et al.*, 1998; Major, D. E. *et al.*, 2003). In the cat, the retinopulvinar projection arises almost exclusively from a single RGC type, the epsilon cell (Leventhal, A. G. *et al.*, 1980; Pu, M. *et al.*, 1994). This is a monostratified ON type with relatively large cell body, a large sparse dendritic field, and a sustained light response. In primates, a more diverse mix of RGC inputs to the pulvinar has been reported, apparently including some midget and parasol cells as well as other types (Cowey, A. *et al.*, 1994). Sparse input from optic fibers has also been reported in the vicinity of anterodorsal thalamic nuclei (Conrad, C. D. and Stumpf, W. E., 1975; Itaya, S. K. *et al.*, 1986; Cooper, H. M. *et al.*, 1993; Major, D. E. *et al.*, 2003) and the medial geniculate nucleus (Matteau, I. *et al.*, 2003).

1.25.4.3 Superior Colliculus

The superior colliculus is, aside from the LGN, the most prominent and well-studied target of retinofugal fibers. To summarize briefly, the superior colliculus is a laminated structure of the midbrain tectum. There is a topographically ordered and bilateral retinal projection to the superficial collicular layers, whereas the deeper layers translate spatiotopic visual and other sensory inputs into motor commands for reorienting the eyes and head. The retinal afferents to the superficial layers thus appear to serve, in part, as inputs elements in a visuomotor interface generating gaze shifts to visual targets of interest. Neurons of the superficial collicular layers also provide ascending visual input to the LGNd, pulvinar, and other thalamic visual nuclei. They thus provide a conduit distinct from the main retinogeniculostriate pathway by which retinal information can reach the visual cortex.

Ganglion cells innervating the superior colliculus are structurally and functionally heterogeneous in every mammalian species studied to date. Indeed, in rodents and rabbits it appears that nearly all RGCs innervate the colliculus (Chalupa, L. M. and Thompson, I., 1980; Vaney, D. I. *et al.*, 1981b; Linden, R. and Perry, V. H., 1983; Hofbauer, A. and Drager, U. C., 1985). In the cat, the fraction of all RGCs innervating the colliculus is closer to one half (Wässle, H. and Illing, R. B., 1980; Stein, J. J. *et al.*, 1995) while in primates the fraction is as low as one tenth (Perry, V. H. and Cowey, A., 1984). The smaller fractions of RGCs innervating cat and primate colliculus reflect the fact that a few very abundant RGC types make little if any contribution to this pathway. Specifically, most beta (X) cells in the cat and most midget (P) and parasol (M) cells in primates apparently lack collicular projections (e.g., Hoffmann, K. P., 1973; Cleland, B. G. and Levick, W. R., 1974b; Stone, J., 1983; Perry, V. H. and Cowey, A., 1984; Leventhal, A. G. *et al.*, 1985; Rodieck, R. W. and Watanabe, M., 1993; Tamamaki, N. *et al.*, 1995). In cats, it appears that virtually all ganglion cells other than beta cells innervate the superior colliculus (Stein, J. J. and Berson, D. M., 1995), and a variety of specific RGC types have been specifically shown to contribute in cats (Leventhal, A. G. *et al.*, 1985; Berson, D. M. *et al.*, 1998; 1999; Isayama, T. *et al.*, 2000), primates (Leventhal, A. G. *et al.*, 1981; Rodieck, R. W. and Watanabe, M., 1993; Dacey, D. M., 2004), ferrets (Vitek, D. J. *et al.*, 1985; Wingate, R. J. *et al.*, 1992), and squirrels (Rivera, N. and Lugo, N., 1998).

Most of the highly conserved RGC types reviewed earlier in this chapter contribute to the retinocollicular projection. This is particularly well documented for the alpha cell or its physiological equivalent, the Y or brisk-transient cell. This was first established in the cat visual system (Hoffmann, K. P. 1973; Cleland, B. G. and Levick, W. R., 1974b; Stone, J., 1983; Wässle, H. and Illing, R. B., 1980; Bowling, D. B. and Michael, C. R., 1980; Itoh, K. *et al.* 1981; Tamamaki, N. *et al.*, 1995) but has been confirmed in ferret (Vitek, D. J. *et al.*, 1985; Wingate, R. J. *et al.*, 1992), rat (Linden, R. and Perry, V. H., 1983; Dreher, B. *et al.*, 1985), mouse (Hofbauer, A. and Drager, U. C., 1985), hamster (Lau, K. C. *et al.*, 1992), and rabbit (Vaney, D. I. *et al.*, 1981a). As noted above (see Section 1.25.3.5), the absence of a substantial collicular projection from primate parasol cells led some to question whether they were homologous to the alpha cells of other mammals, and recent work has identified a distinct RGC type with features much more closely resembling those of cat alpha cells, including prominent collicular projections.

Few if any beta (X) cells contribute to the retinocollicular projection in cats or ferrets (e.g., Cleland, B. G. and Levick, W. R., 1974b; Stone, J. and Fukuda, Y., 1974; Wässle, H. and Illing, R. B., 1980; Stone, J., 1983; Leventhal, A. G. *et al.*, 1985; Wingate, R. J. *et al.*, 1992; Tamamaki, N. *et al.*, 1995). The same is true of primate midget and parasol cells (Schiller, P. H. and Malpeli, J. G., 1977; Leventhal, A. G. *et al.*, 1981; Perry, V. H. and Cowey, A., 1984; Rodieck, R. W. and Watanabe, M., 1993), both of which have been suggested as possible homologs of cat beta cells. Collicular projections have been reported for possible beta-cell homologs in the squirrel (Rivera, N. and Lugo, N., 1998) and for X-like cells in the rabbit (Vaney, D. I. *et al.*, 1981a), but the equivalence of these cells to beta cells is not firmly established.

Ganglion cells of the local edge detector (LED) type appear to make a major contribution to the retinocollicular projection. Cells of this receptive field type have been antidromically activated from the colliculus in cat (Cleland, B. G. and Levick, W. R., 1974a; Stone, J. and Fukuda, Y., 1974), rabbit (Vaney, D. I. *et al.*, 1981a), and primate (Schiller, P. H. and Malpeli, J. G., 1977). Studies combining retrograde labeling and dye filling have demonstrated collicular projections of RGCs with LED-like morphology in cat (Berson, D. M. *et al.*, 1998), ferret (Wingate, R. J. *et al.*, 1992), and primate (Rodieck, R. W. and Watanabe, M., 1993). The projection to the colliculus makes functional sense in that this structure generates gaze shifts to salient objects in the environment, and LEDs seem well suited for detecting object motion against a stable background while filtering out other sorts of image motion, such as translations due to gaze shifts or optic flow during locomotion.

Both types of DS cells also appear to contribute to the retinotectal projection. Input from ON–OFF DS cells to the colliculus were inferred from intracollicular recordings in the squirrel (Michael, C. R., 1972) and from antidromic activation of these cells from the superior colliculus in rabbits and cats (Cleland, B. G. and Levick, W. R., 1974a; Stone, J. and Fukuda, Y., 1974; Vaney, D. I. *et al.*, 1981a). Regarding the other directionally selective type, the ON-DS cell, Buhl E. H. and Peichl L. (1986) suggested on anatomical grounds that these cells lacked collicular projections and that most of the very rare RGCs without tectal projections (1%) were of this type. However, this conclusion appears to be at odds with the electrophysiological (Vaney, D. I. *et al.*, 1981a) and anatomical data (Peichl, L. *et al.*, 1987a), suggesting that ON-DS do contribute to the retinotectal projection. Melanopsin RGCs appear to provide at least a sparse input to the colliculus (Hattar, S. *et al.*, 2006; Morin, L. P. *et al.*, 2003).

Axons originating from different types of RGCs apparently terminate at different depths within the superficial collicular layers (Hoffmann, K. P., 1973; Marrocco, R. T., 1978; Itoh, K. *et al.*, 1981; Freeman, B. and Singer, W., 1983; Sachs, G. M. and Schneider, G. E., 1984; Hofbauer, A. and Drager, U. C., 1985; Berson, D. M., 1987; Mooney, R. D. and Rhoades, R. W., 1990). However, only the broad outlines of this arrangement have been explored to date. A remarkable degree of laminar segregation of optic afferents by functional or anatomical type has been documented in nonmammalian optic tectum (e.g., Maturana, H. R. *et al.*, 1960; Yamagata, M. *et al.*, 2006), and it would be of interest to learn whether a similar segregation holds for the dozen or more RGC types innervating the mammalian colliculus. The potential functional significance of this laminar arrangement of retinal afferents lies in its potential to route specific retinal signals to different populations of tectal cells with distinct output projections, since these output populations exhibit a parallel sublaminar organization (reviewed by May, P. J., 2005).

1.25.4.4 Accessory Optic System

The accessory optic system (AOS) consists of a scattered collection of small retinorecipient midbrain nuclei and the fascicles of optic fibers, termed accessory optic tracts, that innervate them. The AOS plays a key role in mechanisms of retinal image stabilization (for review, see Simpson, J. I., 1984; Giolli, R. A. *et al.*, 2005; Simpson, J. I. *et al.*, 1988a; 1988b). In particular, the AOS nuclei function as an essential conduit for whole-field retinal motion (retinal slip) signals that reach the vestibulocerebellum, through which they drive the slow phase of optokinetic nystagmus (for review, see Simpson, J. I. *et al.*, 1988c). This visuomotor reflex works complementarily and synergistically with signals from the vestibular semicircular canals to stabilize the retinal image during self-motion. Most mammals have three terminal nuclei of the accessory optic system (dorsal, lateral, and medial) which differ in their directional preferences for retinal whole-field motion (see Soodak, R. E. and Simpson, J. I., 1988; van der Togt, C. *et al.*, 1993). The nucleus of the optic tract (NOT), a component of the pretectal region, appears to be another element in this functional system (see below).

Retinal inputs to the AOS have been extensively studied by anterograde tracing methods in a wide variety of mammals, including primates, rodents, cats, and rabbits (Pickard, G. E. and Silverman, A. J., 1981; Weber, J. T., 1985; Cooper, H. M. *et al.*, 1990; Cooper, H. M. *et al.*, 1993; Miura, M. *et al.*, 1997; Pak, M. W. *et al.*, 1987; Ling, C. *et al.*, 1998; Telkes, I. *et al.*, 2000; Major, D. E. *et al.*, 2003; Matteau, I. *et al.*, 2003). There is overwhelming evidence that most, if not all, of this retinal input arises from a single type of RGC, the ON-DS cell. Oyster C. W. *et al.* (1972) noted that the directional selectivity and low-pass velocity tuning of ON-DS cells were well suited to the functional requirements of the optokinetic system. As noted above (see Section 1.25.3.2), Buhl E. H. and Peichl L. (1986) found that RGCs retrolabeled from the rabbit MTN formed a single morphological type, and structure–function studies by Amthor F. R. *et al.* (1989a) convincingly linked this anatomical type to the ON-DS receptive-field type.

Recordings from the accessory optic nuclei revealed large directionally selective receptive fields that could be easily assembled from convergent inputs from ON-DS RGCs (Soodak, R. E. and Simpson, J. I., 1988). Different directional preferences among the three AOS terminal nuclei suggested selective inputs from the three subtypes of ON-DS cells, which are themselves defined by their directional preferences (see above). In a remarkable insight, Simpson and colleagues observed that the preferred directions of each of the three ON-DS RGC subtypes and its associated AOS neurons was matched to the direction of retinal image motion that result when the head is rotated about the preferred axis of one of the three semicircular canals. This led Simpson and co-workers to conclude that the ON-DS/AOS network functions as "a visual system in vestibular coordinates," preprocessing visual motion signals to facilitate their seamless integration with vestibular representations of head rotation to drive gaze-stabilizing eye movements (Simpson, J. I. *et al.*, 1988b; 1988c).

1.25.4.5 Pretectal Region

The pretectum constitutes a collection of nuclei of the rostrodorsal brainstem lying just in front of the superior colliculus at the transition between midbrain and diencephalon. At least five distinct nuclei are recognized within this region: the NOT, olivary pretectal nucleus (OPN), and the anterior, medial, and posterior pretectal nuclei. These nuclei differ sharply from one another in inputs, outputs, and functional properties. Several of them constitute major targets of retinofugal axons and have been implicated in a variety of visuomotor reflexes, including optokinetic nystagmus (OKN) and the pupillary light reflex. Like the superior colliculus, the pretectum also gives rise to ascending projections to the visual thalamus, through which it may contribute to cortical visual mechanisms. For a thorough review of the relevant literature in this area, the reader is referred to Chapter Pupillary Control Pathways and to other key papers and reviews (Scalia, F., 1972; Scalia, F. and Arango, V., 1979; Clarke, R. J. and Ikeda, H., 1985; Pak, M. W. *et al.*, 1987; Gamlin, P. D., 2005; Simpson, J. I. *et al.*, 1988a; Trejo, L. J. and Cicerone, C. M., 1984; Weber, J. T., 1985).

Working out the types of RGCs providing input to the pretectal nuclei has been particularly difficult. This is attributable to the small size, complex boundaries and tight packing of retinorecipient pretectal nuclei. The problem is compounded by the fact that optic fibers within the brachium of the superior colliculus pass very near to or through these nuclei. Thus, RGCs retrolabeled or antidromically activated from the pretectal region may include some that merely send axons through the region *en route* to the

colliculus. Despite these impediments, strong evidence has been developed for inputs from specific RGC types to two pretectal nuclei, the NOT and the OPN.

At least a part of the NOT is closely associated with the accessory optic system (AOS), and is sometimes included with it (Gamlin, P. D., 2005). As just discussed, the AOS serves as a key link between the retina and brainstem circuits generating OKN. Cells in the NOT of many species have been shown to exhibit the same sort of directional preference for whole-field motion observed in cells of the AOS (see Gamlin, P. D., 2005 for review). In their preference for temporonasal slip, they most closely resemble the cells of the DTN, an AOS nucleus with which it is contiguous. The great majority of RGCs retrolabeled from the rabbit NOT have the morphology of the ON-DS type, though a few cells resembling ON–OFF DS cells were also labeled (Pu, M. L. and Amthor, F. R., 1990b). NOT cells functionally resembling neurons of the AOS appear segregated within the NOT, and other sectors of the nucleus exhibit distinctive properties and connections (Gamlin, P. D., 2005).

The olivary pretectal nucleus is an essential synaptic waystation in the neural circuit for the pupillary light reflex. As reviewed by Gamlin P. D. (2005 and Chapter Pupillary Control Pathways), the OPN receives direct retinal input and projects to the parasympathetic preganglionic nucleus mediating pupillary constriction. The dominant retinal input to the OPN appears to come from melanopsin RGCs (Hattar, S. *et al.*, 2002; 2006; Hannibal, J. and Fahrenkrug, J., 2004; Dacey, D. M. *et al.*, 2005; Gamlin, P. D. *et al.*, 2007), but other RGCs of unknown type appear to innervate this nucleus as well (Hattar, S. *et al.*, 2006). There are strong similarities between the melanopsin RGCs and OPN neurons in their tonic encoding of retinal irradiance (Clarke, R. J. and Ikeda, H., 1985; Berson, D. M. *et al.*, 2002; Dacey, D. M. *et al.*, 2005; Trejo, L. J. and Cicerone, C. M., 1984; Gamlin, P. D., 2005; Gamlin, P. D. *et al.*, 2007; see Chapter Pupillary Control Pathways). The persistence of pupillary responses when rod and cone photoreceptors are silenced pharmacologically or genetically is attributable to the intrinsic photosensitivity of the melanopsin RGCs (see Chapters Melanopsin Cells and Pupillary Control Pathways).

Beyond the OPN and the part of the NOT linked to the AOS, relatively little is known about the RGC types innervating the remaining pretectal nuclei. In cats, there is good evidence for inputs from both alpha (Y) and beta (X) cells (Cleland, B. G. and Levick, W. R., 1974b; Schoppmann, A. and Hoffmann, K. P., 1979; Bowling, D. B. and Michael, C. R., 1980; Stone, J., 1983; Leventhal, A. G. *et al.*, 1985; Koontz, M. A. *et al.*, 1985; Tamamaki, N. *et al.*, 1995). There is also clearly input to the pretectum from RGCs other than alpha or beta cells, judging from their small somata and slowly conducting axons (Schoppmann, A. and Hoffmann, K. P., 1979; Stone, J., 1983; Leventhal, A. G. *et al.*, 1985; Rodieck, R. W. and Watanabe, M., 1993; Perry, V. H. and Cowey, A., 1984; Koontz, M. A. *et al.*, 1985; Wingate, R. J. *et al.*, 1992; Young, M. J. and Lund, R. D., 1998). However, well-characterized RGC types have not yet been identified within this group.

1.25.4.6 Hypothalamic Region

The main target of the retinohypothalamic tract is the SCN, which is the master pacemaker for circadian rhythms. This pathway is essential for the resetting of circadian phase by light and, indirectly, for the photic regulation of pineal melatonin synthesis. Detailed information about SCN and the properties of its retinal input may be found in Chapters The Suprachiasmatic Nucleus and Melanopsin Cells, and in Section 1.25.3.1. To summarize, it is well established that the primary source of retinal input to the SCN derives from melanopsin-expressing ganglion cell photoreceptors, with a minor input from other as yet uncharacterized RGCs (Gooley, J. J. *et al.*, 2001; 2003; Berson, D. M. *et al.*, 2002; Hannibal, J. *et al.*, 2002; Hannibal, J. and Fahrenkrug, J., 2004; Hattar, S. *et al.*, 2002; 2006; Morin, L. P. *et al.*, 2003; Sollars, P. J. *et al.*, 2003).

Sparse retinal projections have been shown to reach a wide variety of hypothalamic targets other than the SCN in a wide variety of mammalian species (Johnson, R. F. *et al.*, 1988; Costa, M. S. *et al.*, 1999; Mick, G. *et al.*, 1993; Mikkelsen, J. D., 1992; Mikkelsen, J. D. and Serviere, J., 1992; Pickard, G. E. and Silverman, A. J., 1981; Reuss, S. and Decker, K., 1997; Youngstrom, T. G. *et al.*, 1991; Hattar, S. *et al.*, 2006; Leak, R. K. and Moore, R. Y., 1997; Hannibal, J. and Fahrenkrug, J., 2004; Levine, J. D. *et al.*, 1991; 1994; Abizaid, A. *et al.*, 2004). These include the preoptic region, supraoptic nucleus, lateral and anterior hypothalamic nuclei, subparaventricular zone, and retrochiasmatic area. The functional roles of these retinal outputs are obscure in many cases, but are likely to include modulation of sleep propensity,

neuroendocrine function, and circadian regulation. Melanopsin RGCs have been shown to contribute to many of these projections, although there are clearly also inputs from other unknown RGC types (Leak, R. K. and Moore, R. Y., 1997; Gooley, J. J. *et al.*, 2003; Hattar, S. *et al.*, 2006).

1.25.4.7 Other Targets

In addition to the sparse retinal projections to various dorsal thalamic nuclei noted above, weak retinal inputs have been detected in a variety of limbic, epithalamic, and brainstem sites. These include the amygdala, piriform cortex, bed nucleus of the stria terminalis, zona incerta, perihabenular region, periaqueductal gray, and dorsal raphe nuclei (Foote, W. E. *et al.*, 1978; Pickard, G. E. and Silverman, A. J., 1981; Cooper, H. M. *et al.*, 1993; Elliott, A. S. *et al.*, 1995; Qu, T. *et al.*, 1996; Morin, L. P. and Blanchard, J. H., 1998; Fite, K. V. *et al.*, 1999; 2003; Matteau, I. *et al.*, 2003; Hattar, S. *et al.*, 2006). In general, the ganglion cells from which these projections arise have been characterized only by retrograde transport, which does not permit identification of specific RGC types. However, at least some of these projections have been traced in part to melanopsin RGCs (Hattar, S. *et al.*, 2006), suggesting that these targets may participate in non-image-forming visual networks driving physiological responses to the presence or absence of daylight.

1.26.1 Advantages of a Mobile Pupil

The normal human pupil can change diameter from 8 to 1.5 mm, which corresponds to approximately a 28-fold change in area. Thus, the movement of the iris can account for almost 1.5 log unit variation in retinal irradiance. Although the visual system can operate over a 10 log unit range of lighting levels through the process of adaptation, it can take several minutes for optimum sensitivity to return after an abrupt increase or decrease in retinal illumination. The rapid control of retinal irradiance by the iris allows the visual system to more quickly regain optimal sensitivity by dampening fast changes in ambient lighting levels and requiring less retinal adaptation to a given change in environmental lighting levels (Woodhouse, J. M. and Campbell, F. W., 1975; Hood, D. and Finkelstein, M., 1986).

However, changes in pupil size affect not only retinal illumination, but also diffraction, optical

aberrations, and depth of focus of the eye. These factors differentially affect visual performance, and given changing environmental lighting conditions and visual tasks, the nervous system continuously modulates pupil diameter for optimal visual performance.

The diffraction of light rays by an aperture is a major limiting factor in the resolution of an image in any optical system. The amount of disruption in image quality caused by diffraction at a circular aperture decreases as the size of the opening increases. Therefore, as pupil diameter increases, there is decreased degradation in retinal image quality caused by diffraction (Campbell, F. W. and Green, D. G., 1965; Fry, G. A., 1970; Charman, W. N., 1995). In contrast to diffraction, the image degrading effects of optical aberrations increase as aperture diameter increases. Therefore, as pupil diameter increases, the degradative effects of optical aberrations also increase and offset the benefits gained by reduced diffraction at larger pupil diameters (Liang, J. and Williams, D. R., 1997; Schwiegerling, J., 2000). Over the normal range of pupillary diameter, diffraction impacts image quality less than optical aberration, and the optimal pupil diameter is therefore approximately between 2 and 4 mm (Jenkins, T. C. A., 1963; Westheimer, G., 1964; Campbell, F. W. and Gubisch, R. W., 1966).

Along with diffraction and optical aberrations, defocus is an important determinant of retinal image quality. Although the iris does not refract or focus light, it influences the depth of field of the eye. Depth of field is the range of distance in depth in which objects appear to be in focus. For example, when one reads a book, the power of the crystalline lens of the eyes changes in order to bring the text on the page into focus through a process called accommodation. With the eyes accommodated on the book, all objects within a range in front of and behind the book will also appear in focus. This range is called the depth of field and is primarily dependent on both viewing distance and pupil diameter. When viewing distance is held constant, depth of field increases with decrease in pupil diameter, and therefore, pupil diameter can affect the focus of the retinal image (Marcos, S. *et al.*, 1999; Wang, B. and Ciuffreda, K. J., 2006).

Clearly, a mobile pupil allows the nervous system to optimize retinal irradiance, diffraction, ocular aberrations, and depth of focus despite differing conditions and visual tasks. For example, across a range of daylight (photopic) luminances, pupil size corresponds to that required for the highest visual acuity (Campbell, F. W. and Gregory, A. H., 1960), and the maximal information capacity of the retinal image (Laughlin, S. B., 1992; Hirata, Y. *et al.*, 2003). On the other hand, under low-light (scotopic) conditions in which poorer retinal image quality can be tolerated due to the lower resolution of rod photoreceptors, the pupil dilates sufficiently to maximize retinal illumination. Further evidence for the optimization of pupil diameter for differing visual tasks is evident in the pupillary near response (PNR). When viewing distance changes from far to near, the pupils constrict to increase the field of view and reduce retinal image defocus. This compensates for the decrease in effective field of view that naturally occurs when viewing distance decreases (see Section 1.26.5 for more details).

1.26.2 Overview of the Pathways Controlling Pupil Diameter

A summary diagram of the afferent, central, and efferent pathways controlling pupil diameter is shown in Figure 1. This figure shows the iris musculature innervated by autonomic efferents from both the parasympathetic and the sympathetic components of the ANS. A detailed description of the ANS is beyond the scope of this chapter but is provided by Hockman C. H. (1987) and Robertson D. (2004).

The parasympathetic component of the ANS innervates the sphincter pupillae muscle of the iris. The preganglionic parasympathetic fibers controlling the sphincter pupillae originate from neurons in the Edinger–Westphal nucleus (EW), the autonomic subdivision of the third cranial nerve nucleus, and travel via the third cranial nerve to the ciliary ganglion, which is located within the orbit of the eye (Figure 1). Within the ciliary ganglion, the preganglionic pupilloconstriction neurons form nicotinic, cholinergic synapses with the postganglionic neurons. The axons of these postganglionic neurons leave the ciliary ganglion to enter the eye via the short ciliary nerves and travel to the iris. Here they release acetylcholine, which acts on the muscarinic receptors of the sphincter pupillae (Figure 2) (Hockman, C. H., 1987; Loewenfeld, I. E. and Lowenstein, O., 1993; Oyster, C. W., 1999).

The sympathetic component of the ANS innervates the dilator pupillae muscle. The preganglionic

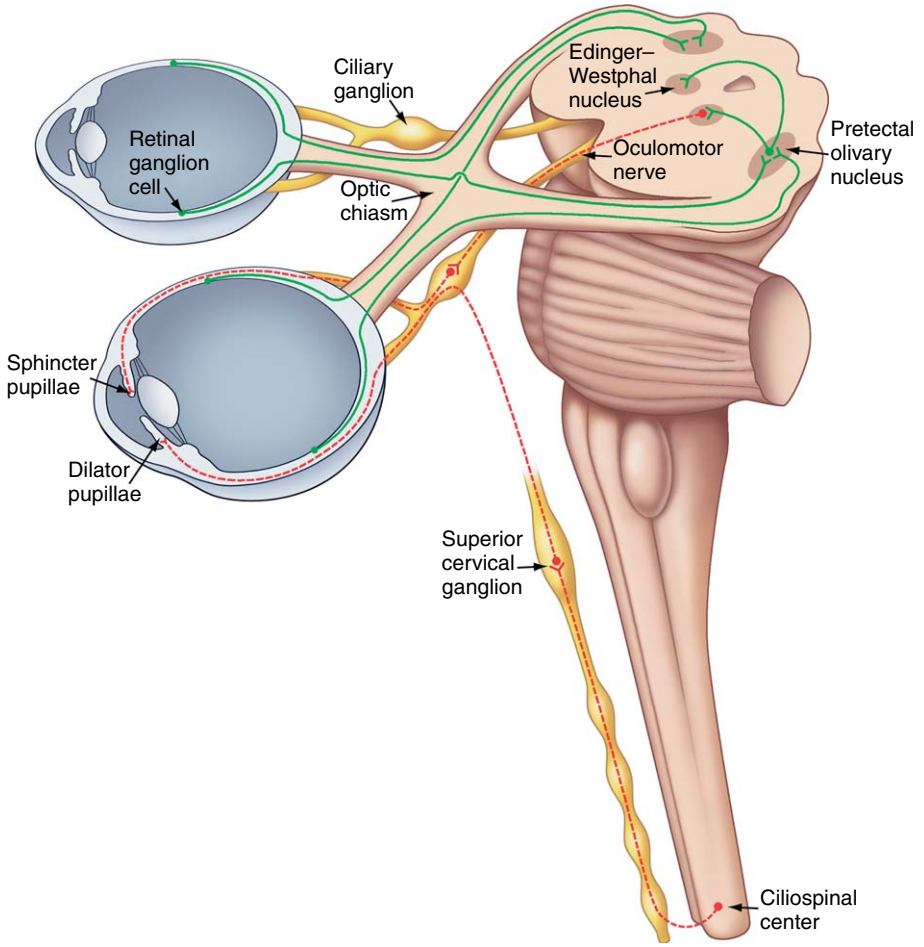

Figure 1 Anatomical drawing showing the direct and consensual pupillary light reflex pathways and the parasympathetic and sympathetic innervation of the iris in primates. The bilateral projection from the retina to the pretectum is also shown. The pretectal olivary nucleus (PON) receives input from the temporal retina of the ipsilateral eye and the nasal retina of the contralateral eye. The PON projects bilaterally to the Edinger–Westphal nucleus, which contains preganglionic parasympathetic pupilloconstriction neurons. The axons of these preganglionic neurons travel in the third cranial nerve to synapse upon postganglionic pupilloconstriction neurons in the ciliary ganglion. The axons of these postganglionic neurons leave the ciliary ganglion and enter the eye via the short ciliary nerves, and then travel through the choroid to innervate the sphincter muscle of the iris. The preganglionic sympathetic pupillodilation neurons are found at the C8-T1 segmental levels of the spinal cord. The axons of these neurons project from the spinal cord via the dorsal roots and enter the sympathetic trunk, and then project rostrally to the superior cervical ganglion where they synapse with the postganglionic neurons. These postganglionic neurons project from the superior cervical ganglion through the neck and carotid plexus and into the orbit of the eye. These fibers enter the eye either by passing through the ciliary ganglion and entering in the short ciliary nerves or by bypassing the ciliary ganglion and entering via the long ciliary nerves (for clarity, only one of these alternative pathways is shown). Upon entering the eye, these axons travel through the choroid and innervate the dilator muscle of the iris.

sympathetic neurons that control pupillary dilation are located in the C8-T1 segments of the spinal cord, a region termed the ciliospinal center of Budge (and Waller). The axons of these preganglionic neurons project to the sympathetic chain and travel in the sympathetic trunk to the superior cervical ganglion (Hockman, C. H., 1987; Kardon, R. H., 2005). Within the superior cervical ganglion, the preganglionic axons form nicotinic, cholinergic synapses with postganglionic pupillodilation neurons. The axons of these postganglionic neurons project from the superior cervical ganglion to the orbit, where they enter the eye via the short and long ciliary nerves and travel to the iris (Figure 1). Here they release norepinephrine, which acts on the adrenoreceptors of the dilator muscle (Figure 2).

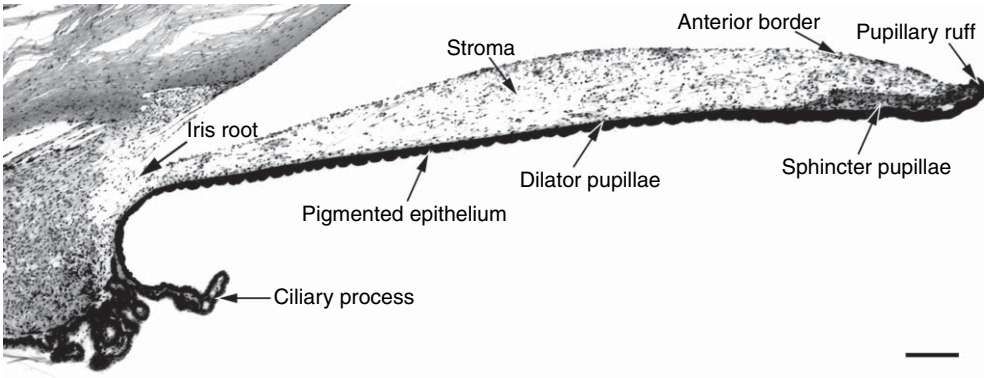

Figure 2 Low-power photomicrograph of a cross section of the macaque iris. Scale bar = 200 μm.

1.26.3 Iris Musculature

In a cross section of the iris, the sphincter pupillae can be seen as an annular band of smooth muscle (100—170 μm thick; 0.7–1.0 mm wide) encircling the pupil (Figure 2).

The sphincter, which is located in the posterior iris immediately anterior to the pigmented epithelium, interdigitates with the surrounding stroma and connects to dilator muscle fibers (see below). The smooth muscle cells of the sphincter are clustered in small bundles and are connected by gap junctions (Bron, A. J. *et al.*, 1997). These gap junctions ensure synchronized contraction of the sphincter muscle. The sphincter receives muscarinic, cholinergic innervation from the short ciliary nerves: postganglionic parasympathetic fibers arising from the ciliary ganglion. The m3 subtype of muscarinic receptor is the predominant receptor subtype expressed by smooth muscle cells of the sphincter pupillae. In the human iris, the m3 receptor subtype comprises 60–75% of the total number of expressed muscarinic receptors, whereas other muscarinic receptor subtypes (m1, m2, m4, and m5) are expressed at lower levels (5–10%) (Gil, D. W. *et al.*, 1997). Binding of acetylcholine to m3 receptors initiates a series of events leading to the activation of phospholipase C (PLC) via G proteins of the Gq family. Activated PLC generates inositol triphosphate (IP_3) and diacylglycerol (DAG) from phosphatidylinositol bisphosphate. The increase in IP_3 elicits the release of Ca^{2+} ions from the endoplasmic reticulum and the influx of extracellular Ca^{2+} ions. The resultant increase in intracellular free Ca^{2+} concentration produces muscle contraction (for review, see Eglen, R. M. *et al.*, 1996). Muscarinic receptor antagonists such as atropine, scopolamine, or tropicamide produce mydriasis, whereas agonists such as pilocarpine, bethanechol, metoclopramide, or oxotremorine produce miosis. The reversible cholinesterase inhibitor, physostigmine, also produces a marked miosis (for review, see Thompson, H. S., 1992).

The dilator pupillae is composed of radially oriented smooth muscle fibers that are myoepithelial in origin. Individual fibers are approximately 50 μm long and 5–7 μm wide. In the pupillary zone, dilator muscle processes fuse with the sphincter pupillae, while peripherally, their processes attach to the ciliary body. Contraction of the dilator muscle pulls the pupillary margin toward the ciliary body (Bron, A. J. *et al.*, 1997). The dilator receives adrenergic innervation from the long ciliary nerves: postganglionic sympathetic fibers arising from the superior cervical ganglion. The alpha 1a adrenoreceptor appears to be the predominant receptor subtype expressed by the smooth muscle cells of the dilator pupillae (Nakamura, S. *et al.*, 1999). Binding of norepinephrine to the alpha 1a adrenoreceptor, a G-protein-coupled receptor, produces muscle contraction through the same signaling cascade (PLC/IP_3) as that in the sphincter pupillae muscle.

Alpha-adrenoreceptor antagonists such as dapiprazole or thymoxamine produce miosis (Thompson, H. S., 1992), as does the more selective alpha 1a-adrenoreceptor antagonist, tamsulosin (Parssinen, O. *et al.*, 2006). The nonspecific adrenoreceptor agonist, phenylephrine, produces mydriasis. Mydriasis is also produced by hydroxyamphetamine and related drugs, which stimulate norepinephrine release from the postganglionic sympathetic nerve endings (Thompson, H. S., 1992).

1.26.4 Pupillary Light Reflex

1.26.4.1 Description

The pupillary light reflex (PLR) is the constriction of the pupil that is elicited by an increase in illumination of the retina. The direct PLR, present in virtually all vertebrates, is the constriction of the pupil in the same eye as that stimulated with light. The consensual PLR is the constriction of the pupil in the eye opposite to the eye stimulated with light. In mammals with laterally placed eyes, such as the rat and rabbit, the direct PLR is more pronounced than the consensual PLR. However, in those mammalian species with frontally placed eyes such as humans and monkeys, the direct and consensual PLR are essentially equal (Loewenfeld, I. E. and Lowenstein, O., 1993). An example of a human consensual PLR produced by two different wavelengths of light is shown in Figure 3.

The PLR has traditionally been divided into two separate pathways based on the clinical manifestations of the defects in this reflex. The afferent pathway is composed of both the retinal cells that project to the pretectum and their recipient neurons that project bilaterally to the EW (Figure 1). The efferent pathway is composed of the preganglionic pupilloconstriction fibers of the EW and their postganglionic recipient neurons in the ciliary ganglion, which project to the sphincter muscle of the iris (Figure 1).

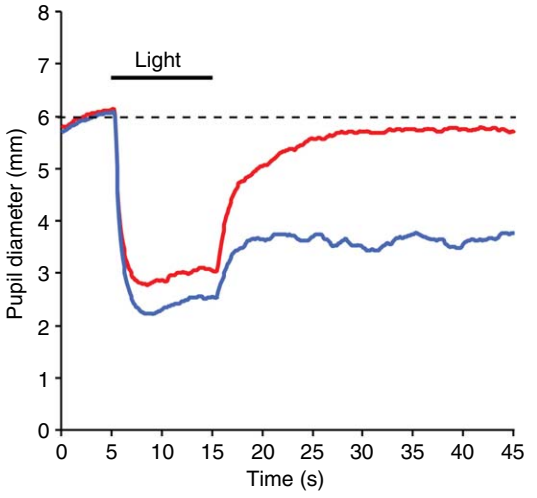

Figure 3 Pupilloconstriction elicited by a 10 s light stimulus of 493 nm wavelength light at 14.0 log quanta $cm^{-2} s^{-1}$ irradiance (blue trace), and 613 nm wavelength light at 14.1 log quanta $cm^{-2} s^{-1}$ irradiance (red trace). Note that a 473 nm stimulus, which effectively activates the intrinsic photoresponse of intrinsically photosensitive retinal ganglion cells (ipRGCs), drives a larger pupillary response than the 613 nm stimulus (red trace), which does not effectively activate the intrinsic photoresponse of ipRGCs at this irradiance level. Also note that the pupilloconstriction induced by the 473 nm light is maintained following stimulus offset.

1.26.4.2 Afferent Pathway

The first, centrally projecting, neurons in the afferent pathway of the PLR are retinal ganglion cells. It has recently been recognized that this reflex in rodents and primates is driven predominantly by a unique subset of intrinsically photosensitive retinal ganglion cells (ipRGCs) that project to the pretectal olivary nucleus (PON), a small nucleus in the pretectum; the pretectum is located in the dorsal lateral aspect of the midbrain at the level of the superior colliculus (Gamlin, P. D., 2005) (Figure 1). Early anatomical studies did not concentrate on the PON specifically, but instead examined all retinal projections to the pretectum, which contains five retinorecipient nuclei. Several of these early studies utilized tracers injected into the vitreous of the eye to anterogradely label all retinal ganglion cell projections to the pretectum. These studies found that the retinal projections to the pretectum were densest to the nucleus of the optic tract and PON and, in primates, were bilateral, with only a slightly denser contralateral component. In contrast, the retinal projection to the pretectum of rodents is predominantly contralateral and only exhibits a moderate ipsilateral component in cats. The ratio of crossed to uncrossed projections of the retinopretectal projections appears to correlate with the ratio of the direct to consensual PLR in mammals.

Other early anatomical studies used retrograde tracing to label pretectally projecting retinal ganglion cells by injecting the tracers into the pretectum. These studies are hard to interpret because fibers projecting to the superior colliculus were also often labeled. Retrograde labeling studies across several different species have found that pretectally projecting cells represented only a small percentage of the total population of ganglion cells (1–6%) and that these cells generally possess small or medium-sized cell bodies and can be classified morphologically as being gamma or W-like. Very few studies were able to successfully target injections exclusively to the PON, and therefore, it is unclear to what extent the retinal cells labeled in these studies actually participate in the PLR. However, an injection

centered on the PON in macaques gave rise to medium-sized labeled neurons, with a few coarse dendrites and extensive dendritic arbors (Perry, V. H. and Cowey, A., 1984). The morphology of these labeled cells is consistent with a newly described retinal cell type that has recently been shown to contribute significantly to the PLR.

1.26.4.2.1 Intrinsically photosensitive retinal ganglion cells

Prior to 2000, it was assumed that the PLR was driven by retinal ganglion cells that received light signals exclusively from rod and cone photoreceptors, which up to that time were the only known photoreceptive cells in the retina. Recent findings suggest that the PLR is driven by ipRGCs, which, unlike any other retinal ganglion cell class, are intrinsically photosensitive. The intrinsic photoresponse of ipRGCs is mediated by the photopigment melanopsin and has been shown to be well fit by a single pigment absorbance spectrum center at 482 nm. In addition to their intrinsic signal, it is clear that ipRGCs receive rod and cone inputs. In response to a pulse of light, intracellular recordings from this cell type show a characteristic transient burst of firing at stimulus onset, which rapidly decays to a plateau of sustained firing that often extends well past stimulus offset. The initial burst of firing is mediated by a rapidly adapting cone-mediated photoresponse and the sustained firing that follows is driven by the intrinsic response of these cells (Berson, D. M., 2003; Fu, Y. *et al.*, 2005).

ipRGCs project to the pretectum of rodents and primates, and it is clear that the confluence of photoreceptive signals impinging on this cell type has a significant impact on pupillary behavior. Several studies have examined the contribution of the separate photoresponses of ipRGCs to the PLR directly. These studies have demonstrated that the intrinsic photoresponse of ipRGCs is necessary but not sufficient to produce a normal PLR in both rodents and primates. Studies investigating the PLR of melanopsin-deficient mice ($Opn4^{-/-}$) have determined that these animals display a PLR, but the pupil fails to constrict maximally in bright lights. Rodents lacking both rod and cone photoreceptors due to retinal degeneration or transgenic manipulation also still display a PLR; however, the reflex has a higher irradiance threshold than normal. When rodless/coneless mice (rd/rdcl) are crossed with $Opn4^{-/-}$ mice to eliminate all potential photoreceptive inputs to ipRGCs, the PLR is completely absent (Berson, D. M., 2003; Fu, Y. *et al.*, 2005).

Recent studies in primates have also shown that the primate PLR is present in the absence of rod and cone input; however, the reflex has a higher retinal irradiance threshold than normal (Gamlin, P. D. *et al.*, 2007). Taken together, these results show that both the intrinsic photoresponse of ipRGCs and classical photoreceptor inputs provide signals of retinal irradiance that drive the PLR. There is evidence that the intrinsic photoresponse compensates for the rapid adaptation of cones and maintains pupilloconstriction during steady-state exposure at all photopic (daylight) illuminance levels. It is still unclear whether the influence of traditional photoreceptors on the PLR is mediated exclusively by the rod and cone inputs to ipRGCs or by other classes of retinal ganglion cells that may to project to the PON.

The intrinsic response of ipRGCs also includes an accumulative irradiance history signal, which can affect pupillary behavior in the absence of overt light stimulation. As noted above, recordings from ipRGCs have shown that these cells possess an ability to encode stimulus irradiance through an elevation of firing rate that extends beyond stimulus offset (Berson, D. M., 2003; Fu, Y. *et al.*, 2005). This sustained firing after stimulus offset appears to be a mechanism for encoding stimulus intensity, as the magnitude and duration of this sustained response varies linearly with stimulus intensity (Dacey, D. M. *et al.*, 2005). This cellular response also appears to influence pupillary responses. Studies of the human PLR have shown that bright light stimuli can produce a prolonged pupillary constriction that persists for up to 20 min, even when the subject is kept in complete darkness following stimulus presentation (Newsome, D. A., 1971; Alpern, M. and Ohba, N., 1972) (Figure 3). It has been determined that this phenomenon is mediated primarily by the intrinsic photoresponse of ipRGCs in primates including humans (Gamlin, P. D. *et al.*, 2007).

1.26.4.2.2 Pretectal olivary nucleus

The second neurons in the afferent pathway of the PLR are luminance neurons within the PON. PON luminance neurons are characterized by tonic firing rates that increase with increase in retinal illuminance.

In primates, these neurons exhibit a transient burst of activity followed by sustained tonic activity in response to increase in retinal illuminance (Figure 4). In addition, the tonic firing rate of these

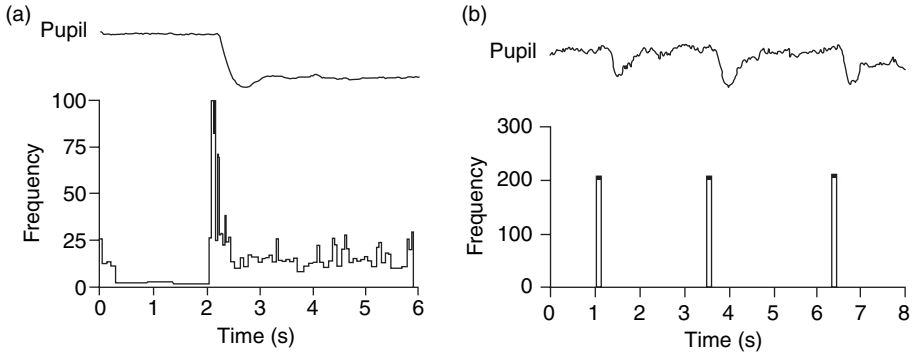

Figure 4 Luminance neurons in the pretectal olivary nucleus (PON) drive the pupillary light reflex. (a) The response of a single neuron is the PON in response to a 100-troland light stimulus. The pupillary response to the same light stimulus is shown in the trace above. (b) Electrical microstimulation at the level of the PON produces pupillary constriction, even in the absence of a light stimulus.

cells is proportional to retinal illuminance over at least a 3 log unit range of stimulus intensities in primates (Gamlin, P. D. *et al.*, 1995) and in rats (Clarke, R. J. and Ikeda, H., 1985b). Although it is clear that these luminance neurons receive inputs from ipRGCs and that the response characteristic of PON luminance neurons to increase in retinal illuminance is reminiscent of that of ipRGCs, it is possible that these neurons may receive input from other types of retinal ganglion cells. In addition to these retinal afferents, the PON also receives significant cortical, ventral thalamic, and midbrain inputs, which may also have a direct influence on the PLR or other pupillary movements. Owing to its importance in the PLR, the best-described efferent projection of the PON is to the EW. However, the PON has also been shown to have a variety of efferent connections that may influence pupillary behavior such as the hypothalamus, pons, and medulla (Gamlin, P. D., 2005).

Electrical microstimulation of the PON in rats and monkeys elicits pupilloconstriction at short latencies (Figure 4(b)), and lesions of the PON in rats produce deficits in pupillomotor function (Gamlin, P. D., 2005). These results provide strong support for models in which luminance neurons within the PON mediate the PLR.

Recently, the characteristics of PON neurons have been more closely examined in the alert primate. This study found that there were three classes of luminance cells in the PON that could be distinguished by their receptive field extent and location. Approximately 40% of the primate PON luminance neurons responded well to stimuli, whether they were presented in either the contralateral or the ipsilateral visual field. These neurons were classified as bilateral neurons. Approximately 30% of PON neurons responded only to stimuli presented in the contralateral visual field. These neurons were classified as contralateral neurons. Finally, 30% of PON neurons responded primarily to stimuli presented at or near the animal's fixation point. These neurons were classified as macular neurons. The mean firing rates of all classes of neurons increased with increase in stimulus size and luminance within their receptive fields. PON luminance neurons of the bilateral and contralateral classes possess very large receptive fields, which exceeded the sizes reported in cats and rats. In addition, while 84% of PON neurons are binocular in the primate, only 22% are reported to be binocular in cats. Thus, it is likely that PON neurons with such extensive, binocular receptive fields are unique to primates, and the existence of such neurons may also explain why the direct and consensual PLR are of comparable magnitudes in primates (Gamlin, P. D., 2005).

Although it has been firmly established that both the PON and the EW (see next section for details) play a critical role in the PLR, there is disagreement as to the route of connectivity between these two nuclei. Some studies propose both a direct connection between PON and EW and an indirect connection via the nucleus of the posterior commissure (NPC) in the rat and in primates, while other studies have reported only the indirect connection via NPC in the cat and tree shrew. A number of studies in primates, using several different tracing techniques, have reported only the direct connection between the PON and the EW (Gamlin, P. D., 2005). Further study will be required to definitively resolve this issue.

1.26.4.3 Efferent Pathway

The efferent leg of the PLR begins with preganglionic pupilloconstriction neurons of the EW that travel via the third cranial nerve to the ciliary ganglion (Figure 1). Within the ciliary ganglion, the preganglionic pupilloconstriction neurons synapse with the postganglionic pupilloconstriction neurons, and the axons of these postganglionic neurons leave the ciliary ganglion to enter the eye via the short ciliary nerves and travel to the iris.

1.26.4.3.1 The Edinger–Westphal nucleus

EW is a distinct nucleus of the midbrain, lying immediately dorsal to the oculomotor complex. It is located just slightly ventral and lateral to the cerebral aqueduct at the level of the superior colliculus (Figure 1). This nucleus was first described in a developmental study of human neuroanatomical material by Edinger L. (1885) and, a short time afterward, in a neuropathological study by Westphal C. (1887). Other early studies involving EW showed that pupilloconstriction could be evoked through the electrical stimulation of EW (Ranson, S. W. and Magoun, H. W., 1933) and determined the precise location of the preganglionic neurons within EW (Warwick, R., 1954). Since these pioneering studies, additional studies have clearly shown in many vertebrate classes that the EW contains the preganglionic neurons that synapse with the postganglionic fibers that innervate the iris sphincter. Further support for the course of the efferent parasympathetic pupillary pathway and the importance of the EW in pupilloconstriction come from electrical stimulation studies in the vicinity of EW that elicited pupilloconstriction in a variety of animal models (Gamlin, P. D., 2000).

The neurophysiology of EW pupilloconstriction neurons has not been extensively studied. This is due to the small size of EW and the small number of pupilloconstriction neurons present, reported to be as few as 10% of the total number of cells in EW (Gamlin, P. D., 2000). A study in cats found that pupilloconstrictor EW neurons displayed firing rates of approximately 8 spikes s^{-1} during maximal pupilloconstriction, but these neurons also displayed transient firing rates with light "on" of up to 28 spikes s^{-1}. A similar finding has been reported in primates, with a pupilloconstrictor neuron displaying a firing rate that ranged from 10 to 25 spikes s^{-1} with a burst-tonic response pattern (Gamlin, P. D., 2000). This firing pattern is similar to both ipRGCs and PON luminance neurons, and it has been postulated that the initial burst at stimulus onset in the pupilloconstriction cells of EW serves to overcome the sluggish nature of the iris musculature.

1.26.4.3.2 The ciliary ganglion

The ciliary ganglion is approximately 3 mm in size and located 2–3 mm posterior to the globe and lateral to the optic nerve. This ganglion contains the cell bodies of the postganglionic pupilloconstrictor neurons, which innervate the sphincter muscle of the iris. Although these neurons receive input primarily from the preganglionic pupilloconstrictor neurons of EW, there is evidence for additional neuronal inputs that may act to modulate this signal (May, P. J. and Warren, S., 1993). Therefore, the ciliary ganglion should not be considered only as a simple relay of preganglionic inputs from EW to the iris, but also as a site of potential neural integration (Gamlin, P. D., 2000).

1.26.4.4 Sympathetic Influences on the Pupillary Light Reflex

Although it is generally agreed that the parasympathetic pathway discussed above is the primary route of pupillary constriction associated with the PLR (Thompson, H. S., 1992; Loewenfeld, I. E. and Lowenstein, O., 1993; Kardon, R., 1995), there is evidence that light may also cause a reduction in the tone of the dilator muscle of the iris via the sympathetic pathway outlined in Figure 1 and thus enhance the PLR. Studies in cats have shown a light-induced inhibition of postganglionic pupillodilation fibers at the level of the long ciliary nerves (Nisida, I. *et al.*, 1960) and preganglionic pupillodilation fibers at the level of the cervical sympathetic nerve (Passatore, M. and Pettorossi, V. E., 1976). These studies found that the pupillodilation fibers were inhibited by light in an intensity-dependent manner, i.e., a more intense light brought about a greater inhibition in firing rate. These findings have not been replicated in primates, in which there is evidence that the sympathetic system plays a tonic role and does not contribute to the dynamics of the PLR (Clarke, R. J. *et al.*, 2003).

Other studies were undertaken to determine the route of the inhibitory light signal to the pupillodilation centers of the spinal cord. By determining the effects of selective lesions at various levels of the central nervous system (CNS) on the light-induced

inhibition of pupillodilation in the long ciliary nerves of cats, Okada H. *et al.* (1960) found that this light signal originated at the level of the pretectum, presumably from one of the retinorecipient nuclei contained within the pretectum. Further lesions in more caudal portions of the CNS suggested that the inhibitory light signal descended from the pretectum bilaterally to the pupillodilation centers of the spinal cord. A more recent series of anterograde labeling studies in the rat support these findings by demonstrating an anatomical connection between the PON and the pupillodilation center of the spinal cord (Klooster, J. and Vrensen, G. F. J. M., 1998).

It is not known whether the light-induced inhibitory signal is carried by pretectal neurons responding to an increase in light intensity, similar to the cells driving the parasympathetic pathway, although this would require an intervening sign-inverting synapse somewhere in the descending pathway. It is possible that the inhibition is a direct result of cells that decrease their firing in response to light. The existence of so-called darkness detector cells has been reported in the pretectum of rats. These cells show a reduction in firing rate in response to increase in retinal luminance (Clarke, R. J. and Ikeda, H., 1985a). Taken together, these findings suggest that the PLR is potentially augmented by a light-induced reduction in tone of the dilator muscle that occurs in conjunction with the increased tone of the sphincter muscle brought about by the parasympathetic pathway.

1.26.5 The Pupillary Near Response

1.26.5.1 Description

The PNR is a pupillary constriction associated with a change in viewing distance from far to near that occurs in primates including humans. When the eyes move from viewing an object at distance to viewing one at near (less than 20 ft away), three oculomotor responses occur. The eyes converge to bring the image of the object onto similar regions of each retina, the refractive power of the crystalline lens is adjusted to bring the image of the object into focus on the retina, and the iris constricts thus reducing the diameter of the pupil. These collective processes are classically referred to as the near response or the near triad.

1.26.5.2 Efferent Pathway of the Pupillary Near Response

The PNR is thought to be driven solely by an increased drive to the sphincter muscle of the iris via the parasympathetic efferent pathway (Kasthurirangan, S. and Glasser, A., 2005). Therefore, the neural control pathway of the PNR shares a common efferent pathway with the PLR, although the afferent inputs responsible for the PNR are more complex. These two reflexes appear to converge at the EW, since the activity of PON luminance neurons is not correlated with the pupil constriction that occurs during near viewing (Zhang, H. *et al.*, 1996). Furthermore, certain clinical neurological conditions are characterized by an intact PNR with the absence of the PLR (light-near dissociation) (Lowenstein, O., 1956).

It is generally accepted that preganglionic neurons in EW drive the PNR as well as the PLR. However, it has not been determined whether separate subpopulations of neurons exist in EW devoted exclusively to either the PLR or the PNR, or whether the same population of neurons drives pupillary constriction in both reflexes, although the latter seems most likely.

1.26.5.3 Afferent Influences on the Pupillary Near Response

Modern investigations into the afferent influences driving the PNR began in the late 1940s with the advent of infrared photographic recordings of the pupil during near viewing. This technique allowed researchers to measure the magnitude of the PNR in near darkness, thus eliminating any artifactual change in pupil diameter induced by decreased retinal illuminance originating from the constriction of the pupil during the response. The aim of these original investigations was to determine whether the PNR was driven primarily by ocular convergence or accommodation, the other two components of the near triad. Early studies found that the PNR was more closely associated with accommodation than with convergence (Fry, G. A., 1945; Knoll, H. A., 1949; Marg, E. and Morgan, M. W., 1949; Marg, E. and Morgan, M. W., 1950; Alpern, M. *et al.*, 1961). Later studies found a greater association with convergence (Backer, W. D. and Ogle, K. N., 1964) and even showed that the PNR could be totally absent during certain blur-driven accommodative responses (Stakenburg, M., 1991; Phillips, N. J. *et al.*, 1992). These conflicting results are likely a product of an

incomplete disassociation between the convergence and the accommodation system during these experiments, as these two systems have been shown to be highly interdependent.

A more modern view of the afferent influences of the PNR has recently emerged, in which the PNR is not seen as resulting from either accommodation or convergence alone, but as a separate output of the neural pathways that drive both accommodation and convergence. This view has followed an increase in the knowledge of the neural circuitry involved in all three oculomotor processes of the near triad. Experiments investigating the interaction between convergence and accommodation lead to the introduction of the dual-interaction model of convergence and accommodation (Semmlow, J. and Heerema, D., 1979; Hung, G. K. and Semmlow, J., 1980; Schor, C. M. and Narayan, V., 1982) (Figure 5). This model proposes that two neural controllers operate in the near triad: one that integrates stimuli for accommodation such as blur and the other that integrates stimuli driving convergence such as disparity between the images on the retinal of each eye (Mays, L. E. and Gamlin, P. D. R., 1995; Schor, M. and Ciuffreda, K. J. 1983).

It is now clear that the PNR is not driven exclusively by either the accommodation controller or the convergence controller, but actually by an interaction of the two controllers (Myers, G. A. and Stark, L., 1990; Takagi, M. *et al.*, 1993). These findings support the view that the outputs of the dual-interaction model drive the PNR in addition to accommodation and vergence (Figure 5). These findings also suggest that the three oculomotor components of the near triad share common afferent influences.

A number of brain areas play a role in controlling the near triad. These include cortical areas, such as extrastriate cortex, parietal cortex, frontal eye fields, as well as the cerebellum and the midbrain. Of particular interest to the PNR is the supraoculomotor area of the midbrain, which lies just dorsal and lateral to the oculomotor nucleus. The supraoculomotor area contains near response cells, which are modulated by both vergence and accommodation and which receive input from both the accommodation and the vergence controllers. These cells project to medial rectus motor neurons and thus contribute to vergence eye movements. It seems likely that these cells also project to EW and are responsible for carrying the signal from the accommodation and the convergence controllers to the preganglionic pupilloconstriction neurons (Schor, C. M. and Ciuffreda, K. J. 1983; Mays, L. E. and Gamlin, P. D. R., 1995; Gamlin, P. D. R., 2002).

1.26.6 Additional Cortical Influences on Pupillary Responses

In addition to cortical afferents mediating the PNR, the pupil is also influenced by both visual and nonvisual cortical regions. These afferents manifest themselves in small changes in pupil diameter measured during presentation of visual stimuli such as colored stimuli and gratings, as well as nonvisual stimuli such auditory tones, and even during higher-order cortical functions such as problem solving. These observations provide clear evidence that cortex exerts an influence on

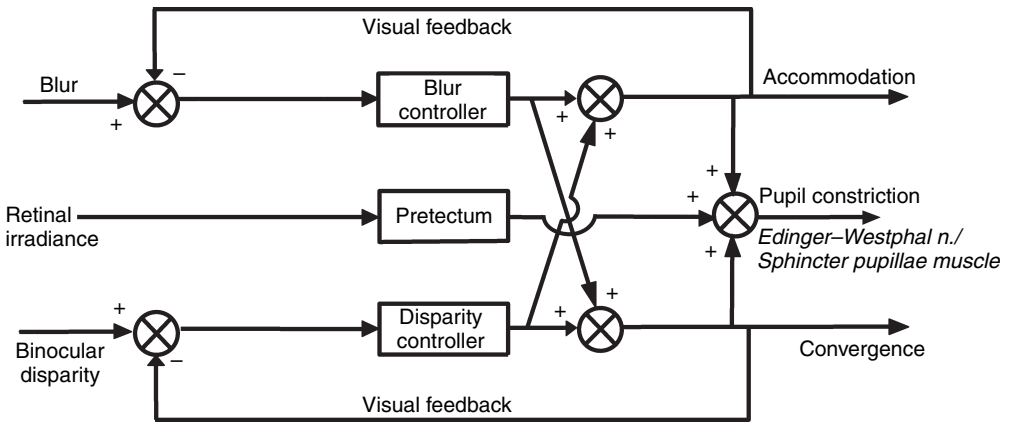

Figure 5 Schematic of the modified dual-interaction model that accounts for the pupillary near response component of the near response triad. This model indicates that the combined output of the accommodation controller and the convergence controller drives the pupillary near response.

pupillary behavior, which cannot be thought of as entirely reflexive in nature.

1.26.6.1 Visually Mediated Cortical Influences on Pupillary Behavior

Recent studies have shown that the pupil responds to complex aspects of visual stimuli such as color, motion, and texture. Slight pupillary constrictions have been shown to occur in both humans and macaques with the presentation of complex visual stimuli, even when the stimuli do not involve a change in viewing distance or retinal illuminance (Barbur, J. L., 1995; Gamlin, P. D. *et al.*, 1998). The three best-described stimulus attributes that produce this effect are color, spatial frequency, and apparent motion. It is clear from physiological and functional imaging studies that these stimulus characteristics are encoded in areas of visual cortex. Furthermore, when these cortically driven pupillary responses are assayed in human subjects with well-documented lesions to cortical areas involved in processing one or more of these stimulus characteristics, a deficit in the concurrent pupillary response is always observed (Barbur, J. L., 1995). In addition, Heywood C. A. and coworkers (1998) have demonstrated in macaques that lesions of rostral inferior temporal cortex but not V4 abolish pupillary responses to chromatically modulated gratings. These findings offer conclusive evidence of an influence of visual cortex on pupil diameter.

Studies have investigated the neural pathways by which visual cortex influences pupil diameter. Research utilizing patients with a well-defined neurological lesion of the midbrain has helped to elucidate one possible neural pathway involved in these responses. The neurological syndrome with which the patients were affected selectively affects the pretectum while sparing the EW. Therefore, the patient's pupils were unreactive to light but maintained a near response. These patients also maintained the pupillary responses to stimulus color and function, and therefore, it seems likely that this cortical influence is mediated by direct cortical inputs to EW (Wilhelm, B. J. *et al.*, 2002).

1.26.6.2 Task-Evoked Pupillary Responses

In the early 1960s, Hess E. H. and colleagues (Hess, E. H. and Polt, J. M., 1960; 1964; Hess, E. H., 1965) published a series of papers that reported modulations in human pupillary diameter associated with complex cognitive processes such as subjective attitudes or mental activity. Later studies failed to produce reliable replication of the findings relating pupillary dynamics to subjective attitudes, although the findings related to mental activity have been replicated and extensively studied. The small pupillary dilations associated with increased mental activity, or task-evoked pupillary responses (TEPRs), have now become a well-established tool of cognitive psychology. These pupillary responses are generally reported to vary in magnitude from 0.2 to 0.7 mm and have been shown to be an accurate reporter of cognitive load across such diverse functions as sensory perception, memory, language, and attention. TEPRs have been repeatedly shown to monotonically vary with the degree of mental activity required by a task as measured by other objective criteria such as reaction time and the extent of cortical activation indicated by positron emission tomography (PET) scan, and this has allowed TEPRs to be utilized successfully to empirically test theories of language processing and intelligence (Beatty, J. and Lucero-Wagoner, B., 2000).

Although the behavioral phenomenon of TEPRs has been extensively studied and quantified, much remains to be elucidated about the precise physiology that drives these responses. Very few, if any empirically driven theories have been developed to explain the neural pathways involved in these responses. It has been suggested that these pupillary responses may be driven by a neuromodulatory effect on pupillary control pathways mediated by noradrenergic projections from the locus coeruleus. The firing rate of neurons in this midbrain nucleus has been shown to correlate with both pupil diameter and task-related events (Aston-Jones, G. and Cohen, J. D., 2005).

1.26.7 Influence of Alertness on Pupillary Behavior

Since the muscles of the iris are controlled by the ANS, environmental or physiological conditions that cause changes in overall autonomic function can have a significant effect on pupillary behavior. Even though the environmental or physiological conditions that produce the change in autonomic tone may not have a direct influence on the visual system, they may still manifest themselves by affecting pupil diameter.

1.26.7.1 Arousal

Situations or stimuli that produce an emotional or a startle response often produce a profound pupillary dilation. This effect is mediated via the hypothalamus, the brain area responsible for the integration of autonomic function. This integration allows for the coordination of the various functions of the ANS and often leads to global changes in the balance between the sympathetic and the parasympathetic branch of the ANS. For example, an unexpected loud noise may produce a startle response that is characterized by increases in heart rate, respiratory rate, and pupil diameter; it is caused by a systemic increase in sympathetic tone mediated through the hypothalamus. This global increase in sympathetic tone can affect pupil diameter via activation of the pupillodilation centers of the spinal cord and inhibition of the pupilloconstriction neurons of EW. Neurons within the hypothalamus project to the preganglionic sympathetic pupillodilation neurons of the thoracic spinal cord. This direct effect of hypothalamic activation on pupil diameter can be shown through microstimulation of the posterior hypothalamus, which often causes rapid pupil dilation. Increase in sympathetic tone can also produce inhibition of pupilloconstriction neurons of EW via the influence of ascending neuromodulatory pathways (Yu, Y. and Koss, M. C., 2004) (see below for more details).

The hypothalamus is also the site at which autonomic function is regulated by the CNS via connections with the limbic system and cortical structures. The limbic system of the brain, which is responsible for emotions and short-term memory, has a direct connection to the hypothalamus and therefore can have significant effects on autonomic balance. Situations or stimuli that produce an intense emotional response are often accompanied by pupillary dilation, which is certainly mediated through limbic connections to the hypothalamus. In addition, cortical influences on the hypothalamus allow a wide variety of stimuli to affect autonomic tone and thus pupil diameter (Hockman, C. H., 1987; Loewenfeld, I. E. and Lowenstein, O., 1993).

1.26.7.2 Sleep

Sleep has a pronounced effect on the ANS, specifically a reduction in sympathetic outflow and an increase in parasympathetic outflow. Given this overall trend, it is not surprising that pupillary behavior during sleep is characterized by prolonged constriction of the pupil. It has been shown that sleep-induced pupillary constriction persists in animals with lesions of the preganglionic sympathetic pupillodilation fibers. This suggests that the sleep-induced pupillary changes are mediated by an activation of the preganglionic parasympathetic pupilloconstriction fibers of the EW. It should be noted that during some phases of sleep, particularly rapid eye movement (REM) sleep, the pupils tonically dilate at random intervals. This dilation mirrors the reversal of parasympathetic dominance with sympathetic dominance during the same intervals (Parmeggiani, P. L., 1984).

1.26.7.3 Ascending Neuromodulatory Systems

The ascending neuromodulatory systems of the midbrain and brainstem can have a variety of effects on pupillary behavior. These nuclei are the origin of neuromodulatory fibers, which release dopamine, norepinephrine, histamine, and serotonin at a number of brain areas implicated in pupillary control. These neuromodulatory systems appear to be critical in the regulation of sleep and arousal (Saper, C. B., *et al.*, 2005), as well as autonomic regulation (Boehm, S. and Kubista, H., 2002) and cortical plasticity (Gu, Q., 2002). In addition to these global neuromodulatory effects, all or some of which could have a profound influence on pupillary behavior, there is evidence for a direct inhibition of pupilloconstriction neurons in the EW by adrenergic neurons originating from the locus coeruleus in a number of animal models (Koss, M. C., 1986). This appears to be an addition mechanism for mydriasis produced by global sympathetic activation. Later studies in humans (Larson, M. D. and Talke, P. O., 2001) and rabbits (Yu, Y. and Koss, M. C., 2004) have failed to find that this direct noradrenergic inhibition of pupilloconstriction neurons, and it has been suggested that this effect is mediated by the dopaminergic neurons in these species (Yu, Y. and Koss, M. C., 2004). Drugs that agonize or antagonize these neuromodulatory neurotransmitters have been found to differentially affect pupillary behavior in a wide range of animal models and human studies. These differential effects are most likely due to the both interspecies variability in the projections of these neuromodulatory fibers (Gu, Q., 2002) and the differential activation of multiple brain areas implicated in pupillary behavior due to the extensive projections of these neuromodulators.

1.26.8 Clinical Significance of Pupillary Abnormalities

The PLR and PNR are commonly used clinical measures of visual and neurological functions. Due to the ease with which these responses can be elicited in a clinical setting, their assessment provides a rapid evaluation of certain critical brain functions. The varied nature of the brain areas that these reflexes traverse allows the clinician to assess retinal, midbrain, and autonomic functions concurrently with a few straightforward measurements of pupillary functions. This section will provide a broad overview of common pupillary dysfunctions and some of the clinical conditions indicated by each (see Kawasaki, A., 2005, for a more comprehensive review).

1.26.8.1 Dysfunctions in the Light Reflex Pathway

As previously stated, the PLR is driven by a simple, four-neuron reflex arc that passes out of the eye, via the optic nerve, to a series of midbrain nuclei, and back to the iris of the eye via the oculomotor nerve (Figures 1 and 6).

For diagnostic purposes, abnormalities of the pupil are traditionally classified as afferent or efferent defects. These divisions are based on whether the lesion involved occurs in the afferent of the efferent leg of the PLR. Afferent defects are indicative of conditions affecting the retina or optic nerve, whereas efferent defects are indicative of autonomic dysfunction or conditions affecting the oculomotor nerve.

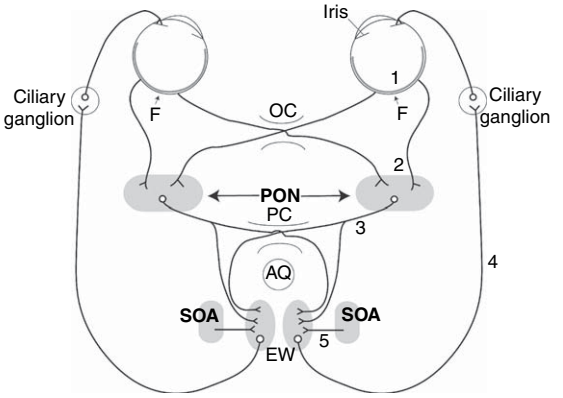

Figure 6 Schematic diagram of the direct and consensual pupillary light pathways in primates including humans. AQ, aqueduct; EW, Edinger–Westphal nucleus; F, fovea; OC, optic chiasm; PC, posterior commissure; PON, pretectal olivary nucleus; SOA, supraoculomotor area.

Afferent defects in the PLR are characterized by an asymmetry in the pupillary response between the two eyes in response to a brief flash of light (Thompson, H. S., 1992; Digre, K. B., 2005). This relative afferent pupillary defect (RAPD) is caused by a difference in the overall light sensitivity of one retina versus the other (Figure 6, pathway 1). When a light is presented to one eye, the neural impulses generated travel to each PON via the optic nerve and therefore generate both a direct and a consensual light response (Figure 6, pathway 2). If the magnitude of the pupillary response differs when the same light in shown in the other eye, this indicates a dysfunction in the visual pathway at the level of the retina or optic nerve in the eye with the lesser response, as the light is less efficient at generating a response in that eye. The presence of an RAPD is a primary symptom of acute disorders of the retina and optic tract, such as optic neuritis, retinal detachment, and retinal vein occlusion. An RAPD is also observed in many of the major diseases of the retina such as glaucoma and macular degeneration, although it is not the primary indicator of these conditions (Thompson, S. H. and Miller, N. R., 1998).

As stated previously, a significant portion of the neural pathway that drives the PLR is located in the midbrain, for example, EW and PON. This midbrain segment of the reflex allows the PLR to be used as a clinical assessment of overall midbrain function (Figure 6, pathway 3). Various midbrain lesions can produce abnormalities in the PLR, which are characterized by an absence or attenuation of the light reflex in one or both eyes, even when a constant, bright stimulus is used. Unless the lesion is small and localized to the pretectum or EW, the PLR deficits will present secondarily to other, more prominent neurological defects. This component of the reflex also allows the PLR to be used to evaluate overall brain function in unconscious or semiconscious patients. Not only does the PLR give a static measure of brain function in these patients, but it is also an important clinical tool used to assess the prognosis and progression of comatose patients and victims of severe head trauma (Thompson, S. H. and Miller, N. R., 1998).

Efferent defects of the PLR are most often characterized by a dissymmetry in the size of the two pupils under steady-state illumination, which is termed anisocoria. Since pupil diameter at any given time is determined by the relative activation of the iris sphincter and dilator muscles, if the relative drive on these two muscles is different in each eye, then anisocoria is produced. This unequal drive can

be caused by a specific lesion that blocks the outflow of neural impulses from EW to the sphincter, or from the superior cervical ganglion to the dilator muscle of one eye (Figure 6, pathway 4). More commonly, anisocoria is caused by a unilateral global dysfunction in either the sympathetic or the parasympathetic branch of the ANS. Therefore, the presence of anisocoria is indicative of disorders of the ANS such as familial dysautonomia and Horner's syndrome, as well as acute disturbances of ocular parasympathetic input such as those caused by basal meningitis and oculomotor nerve palsies (Thompson, S. H. and Miller, N. R., 1998).

1.26.8.2 Dysfunctions in the Near Response Pathway

The PNR is also regularly clinically utilized as a diagnostic tool. The PLR and PNR share a common efferent path from the midbrain to the iris, but due to differing afferent pathways, it is possible to retain one functional reflex in the absence of the other. This condition is called light-near dissociation and is a classic symptom of neurosyphilis (Lowenstein, O., 1956), although a variety of other conditions can also cause this phenomenon, e.g., multiple sclerosis (Loewenfeld, I. E., 1969), neurosarcoidosis (Poole, C. J., 1984), and diabetes mellitus (Dacso, C. C. and Bortz, D. L., 1989). The PNR is often assessed in conjunction with the PLR, as it provides insight into the source of any observed defects in the PLR (Digre, K. B., 2005). Modern neuroimaging techniques have shown the probable site of lesion that leads to the phenomenon of light-near dissociation can be localized to the periaqueductal gray (PAG) matter of the midbrain (Poole, C. J., 1984; Dacso, C.C. and Bortz, D. L., 1989). The PAG lies dorsal and lateral to EW, although the posterior to anterior extent of PAG is much more extensive than that of EW. It is likely that a lesion in the PAG interrupts fibers of passage from the PON to EW (Figure 6, pathway 3) while sparing the connection between SOA and EW (Figure 6, pathway 5). This would interrupt the afferent pathway of the PLR while maintaining the PNR afferents.

1.26.9 Conclusion

The neural regulation of pupil diameter allows for the adaptation of the optics of the eye to a variety of visual task and environmental conditions. This regulation is mediated by a variety of brain areas that have a variety of sensory inputs and functions. Although the control of pupil diameter is generally thought of as a simple reflexive process, the number and complexity of pupillary control pathways involved in the regulation of pupil diameter imparts an unexpected complexity that is only beginning to be appreciated and fully understood.

1.27.1 The Hypothalamic Suprachiasmatic Nucleus

In response to the ineluctable cycle of day and night, organisms have developed a self-sustaining clock-like mechanism that coordinates biological functions both with one another and with specific times of the day or night. Maynard Johnson was one of the first to describe clearly these clock-like properties in mammals. Under controlled conditions in the laboratory, he recorded the rest/activity behavior of feral mice maintained in either cyclic or constant lighting conditions. He noted that the 24 h rhythm of rest and activity evident under the day/night regimen persisted under conditions of constant light, free-running with a period of only approximately 24 h (Figure 1). This observation prompted him to conclude that "this animal has an exceptionally substantial and durable self-winding and self-regulating clock, the mechanism of which remains to be worked out" (Johnson, M. S., 1939). Although Johnson's account of the mouse rest/activity behavior with a period of ≈24 h under constant environmental conditions was a description of a behavioral circadian rhythm, it was not until 20 years later that Franz Halberg (1959) first used the term circadian (from the Latin circa "about" and dies "day").

Since that early account of a biological clock in the mouse, the identification of the hypothalamic suprachiasmatic nucleus (SCN) as the primary circadian oscillator in the mammalian brain and of the retinofugal pathways by which environmental day/night information is conveyed to the SCN have been firmly established (Klein, D. C. *et al.*, 1991). Remarkably, the retinal efferents that transmit environmental irradiance signals to the circadian clock in the SCN consist primarily of axons of a recently discovered novel class of mammalian photoreceptor, the intrinsically photosensitive retinal ganglion cell (ipRGC) (Berson, D. M., 2003).

In this review of the SCN, we begin with a brief account of the molecular mechanisms underlying circadian rhythm generation. Following that introduction, the discussion focuses primarily on the light input pathways to the SCN, the mechanisms by

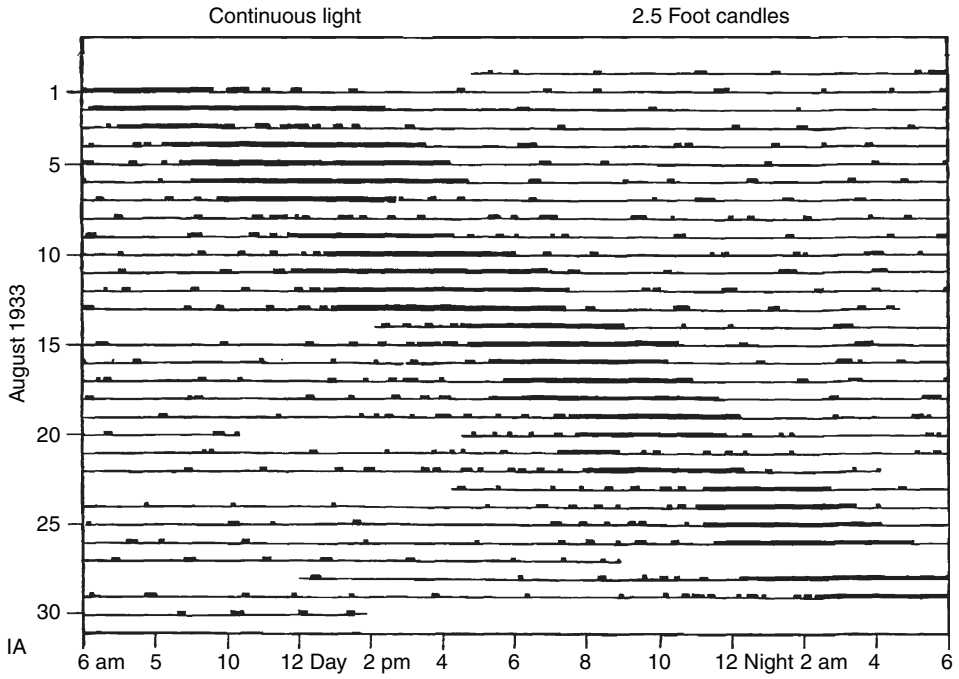

Figure 1 Activity record of a white-footed mouse (*Peromyscus leucopus*) maintained in dim constant light. Activity was recorded as the movement of a suspended cage traced onto smoked paper on a kymograph drum turned by a clockwork. Blocks of black represent cage movement corresponding to mouse activity. The record shows a well-defined circadian rhythm of activity with a period of approximately 24.7 h. Adapted from Johnson, M. S. 1939, Effect of continuous light on periodic spontaneous activity of white-footed mice (Peromyscus). J. Exp. Zool. 82, 315–328, with permission from John Wiley & Sons, Inc.

which these inputs entrain the SCN circadian oscillator to the environmental day/night cycle, and modulation of light input to the SCN by serotonergic afferents arising from the median raphe nucleus. We conclude with a brief summary of the anatomical organization of the SCN, its output pathways, and the role of the SCN in the regulation of peripheral clocks.

1.27.1.1 Molecular Components of the Suprachiasmatic Nucleus Circadian Oscillator

Insights into the molecular mechanisms of the circadian clock began with a mutagenesis screen conducted in the fruit fly that identified three mutant alleles of a single gene (*period*) that had the properties of either increasing or decreasing the circadian period or eliminating circadian rhythmicity altogether (Konopka, R. J. and Benzer, S., 1971). Following the discovery of the mammalian homolog of *Per* (Sun, Z. S. *et al.*, 1997; Tei, H. *et al.*, 1997), great strides have been made in defining the interlocking transcriptional/translational feedback loops that are believed to underlie the generation of circadian oscillations in SCN gene expression (Reppert, S. M. and Weaver, D. R., 2002; Lowrey, P. L. and Takahashi, J. S., 2004; Ko, C. H. and Takahashi, J. S., 2006).

At the core of the current working model of the SCN molecular clock are feedback loops involving positive and negative limbs. The transcription factors CLOCK and BMAL1 are believed to be the positive elements in the primary feedback loop. BMAL1 and CLOCK dimerize in the cytoplasm of SCN neurons, and following translocation to the nucleus, they initiate transcription of target genes of the negative feedback loop, including *period* (*Per1*, *Per2*, and *Per3*) and *cryptochrome* (*Cry1* and *Cry2*) by binding to E-box elements within enhancer and promoter sequences of these genes. The primary negative feedback loop results from the translocation of PER:CRY heterodimers back to the nucleus where they repress their own transcription by acting on the CLOCK:BMAL1 complex (Figure 2) (Ko, C. H. and Takahashi, J. S., 2006). Currently, *Bmal1* (also known as *Mop3*) is the only clock gene that appears to be essential for the generation of circadian oscillations in the SCN. *BMAL1*-null mice display arrhythmic locomotor

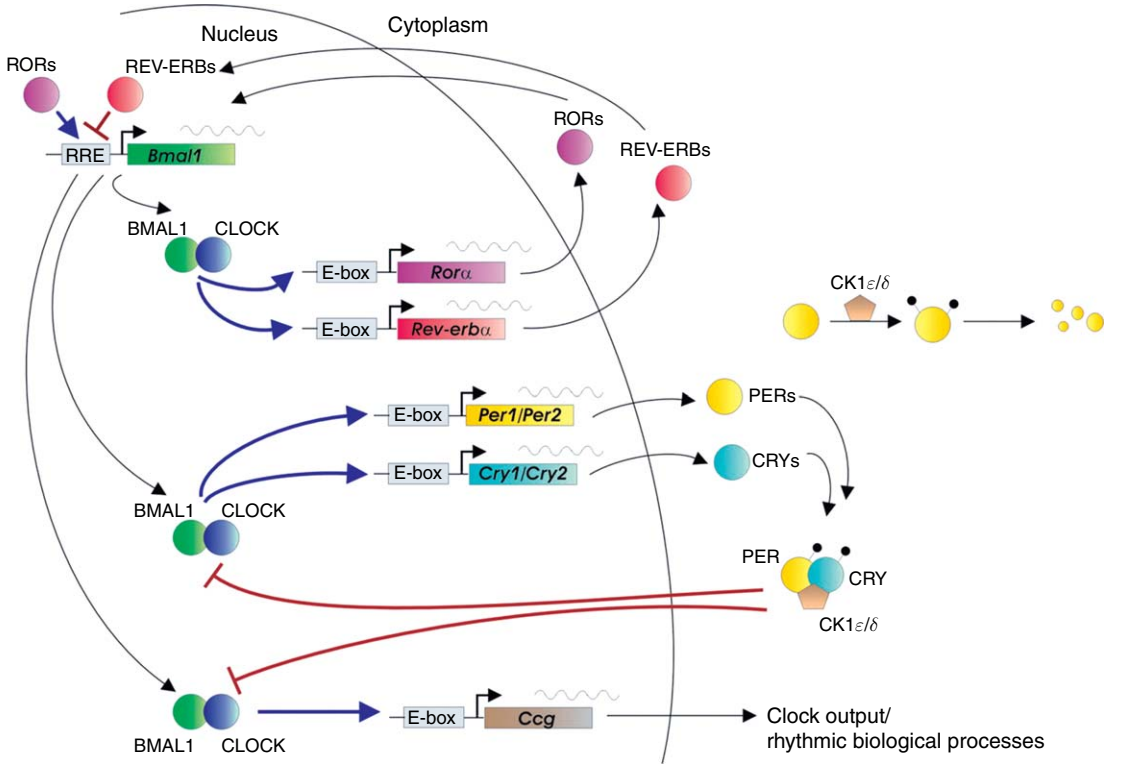

Figure 2 A network model of transcriptional–translational feedback loops that constitutes the mammalian circadian clock. CLOCK and BMAL1 form heterodimers and initiate transcription of *Per1*/*Per2* and *Cry1*/*Cry2*. Per:CRY heterodimers feedback to repress their own transcription. Adapted from Ko, C.H. and Takahashi, J.S. 2006, Molecular components of the mammalian circadian clock. *Hum. Mol. Genet.* 15, R271–R277, by permission of Oxford University Press.

activity immediately when transferred from day/night conditions into a constant dark environment, and the rhythmic expression of *Per1* and *Per2* in the SCN of these animals is abolished (Bunger, M. K. *et al.*, 2000). Two isoforms exist for all other known clock genes (e.g., *Per1* and *Per2*, *Cry1* and *Cry2*), and thus for example, *Per1*- and *Per2*-null mutants each exhibit only modest circadian phenotypes, whereas *Per1*/*Per2* double mutants are completely arrhythmic (Lowrey, P. L. and Takahashi, J. S., 2004).

The circadian behavior of animals with a mutated *clock* gene becomes arrhythmic in constant dark conditions after many days. Based on this gradual loss of rhythmic behavior in constant dark, it was believed initially that *clock* was an essential component of the core SCN molecular clock mechanism (Vitaterna, M. H. *et al.*, 1994). However, subsequent experiments revealed that behavioral circadian rhythmicity is actually retained in *clock* mutant mice when they are maintained under constant light conditions (Spoelstra, K. *et al.*, 2002). Spoelstra K. *et al.* (2002) point out that their new data raise two important questions:

1. Does behavioral arrhythmicity in a mutant mouse reflect an arrhythmic SCN pacemaker or a rhythmic pacemaker that has lost the ability to regulate a behavioral output?
2. Is CLOCK an essential component of the SCN molecular clock mechanism?

The first question was addressed when individual SCN neurons from homozygous *clock* mutant mice were analyzed *in vitro* and were shown to retain their ability to generate circadian rhythms in neural activity, indicating that the SCN is indeed rhythmic in these animals even though behavioral rhythmicity is lost in constant dark conditions (Nakamura, W. *et al.*, 2002). The essential role of CLOCK in circadian rhythm generation was tested by DeBruyne J. P. *et al.* (2006) who generated a *clock*-null mutant mouse; these mice express robust and sustained behavioral circadian rhythms in constant dark conditions, indicating that the CLOCK:BMAL1 heterodimer is not required for SCN circadian clock function. It seems likely that the transcription factor NPAS2, a closely related paralog of CLOCK, assumes the role

of CLOCK in these null mutant mice (DeBruyne, J. P. *et al.*, 2006). However, to date, NPAS2 mRNA has not been detected in the SCN and other possibilities should also be considered until there is evidence for NPAS2 in the SCN (Asher, G. and Schibler, U., 2006).

The period of the circadian oscillation is determined by many factors and is altered by several modulatory transcription factors. For example, *Rev-erbα*, a nuclear orphan receptor, represses the transcription of *BMAL1*, whereas *RORα* (retinoic acid-related orphan nuclear receptor alpha) activates *BMAL1* and alterations in these genes produce small but significant changes in period (Ko, C. H. and Takahashi, J. S., 2006). Post-translational modifications of core clock gene protein products are also clearly important in generating the period of the circadian oscillation observed in the SCN. Casein kinase I epsilon (*CKIε*) appears to be a key player in this process. A widely studied mutation in *CKIε*, the $CKI\varepsilon^{tau}$ mutant, has been shown to cause a loss of kinase function *in vitro*, and the homozygous tau mutant hamster has a circadian locomotor rhythm in constant dark conditions that is 4 h shorter than the period of the wild-type hamster (Lowrey, P. L. and Takahashi, J. S., 2004). Again, emphasizing the evolving nature of the current SCN clock model, Gallego M. *et al.* (2006) provide strong data indicating that $CKI\varepsilon^{tau}$ mutation is actually a highly specific gain-of-function mutation that increases the *in vivo* phosphorylation and degradation of Per1 and Per2. Thus, although impressive progress has been made in unraveling the molecular nature of the SCN circadian clock, there are additional inconsistencies and anomalous observations that do not fit the current clock model that must also be resolved before our understanding of the molecular underpinnings of circadian rhythm generation by SCN neurons is complete (Lakin-Thomas, P. L., 2006; Levi, F. and Schibler, U., 2007).

1.27.1.2 Suprachiasmatic Nucleus Neurons Express a Circadian Rhythm in Neural Activity

When the SCN is surgically isolated from the rest of the brain, rhythmic electrical activity within the hypothalamic island containing the SCN persists, whereas rhythms of multiunit activity in other brain regions that were rhythmic before the isolation of the SCN, as well as behavioral rhythms, are abolished (Inouye, S. I. T. and Kawamura, H., 1979; 1982). These early studies provided important data consistent with the interpretation that the SCN was a circadian oscillator. Recordings made from the SCN *in vitro* showed that the oscillations in neural activity in the hypothalamic island were indeed generated by SCN neurons. The spontaneous electrical activity of SCN neurons in a hypothalamic slice maintained *in vitro* is highest during the subjective day, similar to the time of peak firing of SCN multiunit activity recorded *in vivo* (Meijer, J. H. and Rietveld, W. J., 1989). Recordings from individual SCN neurons in dispersed cell cultures using multielectrode arrays provided definitive evidence that individual SCN neurons generate a rhythm in their rate of action potential firing and thus are competent circadian pacemakers (Welsh, D. K. *et al.*, 1995). The ionic mechanisms underlying rhythmic spontaneous action potential firing of SCN neurons remain to be definitively described (Pennartz, C. M. *et al.*, 2002; Jackson, A. C. *et al.*, 2004; Kononenko, N. I. *et al.*, 2004; Itri, J. N. *et al.*, 2005).

It is clear that the SCN displays circadian rhythms both in gene expression and in the rate of action potential firing. Recent studies at the single-cell level have shown that the phase of the molecular oscillation in SCN neurons is correlated with their action potential firing rate. Using a short-half-life green fluorescent protein (GFP) reporter of *Per1* with quantitative imaging and patch-clamp recording of SCN neurons in an *in vitro* slice preparation, Quintero J. E. *et al.* (2003) were able to define accurately the relationship between *Per1* gene expression and the neurophysiological output of individual SCN neurons. The precise interaction between molecular oscillations in SCN neurons and the membrane activities of these same cells is, however, unclear.

The work of Welsh D. K. *et al.* (1995) using dispersed SCN neurons in culture demonstrated that blockade of neuronal firing with the Na^+ channel blocker tetrodotoxin (TTX) did not affect the circadian rhythm in individual SCN cells, suggesting that neuronal firing was not an essential component of the cellular clock mechanism. However, it has been suggested that depolarization-activated ionic conductances in the membrane of clock neurons are required for circadian pacemaker function and molecular oscillations in core clock genes. By targeting specific clock neurons in *Drosophila* with K^+ channel variants that have a high open probability at resting membrane potential, Nitabach M. N. *et al.* (2002) made these clock cells electrically silent which rendered the flies behaviorally arrhythmic. Surprisingly,

the electrically silent clock cells also lost their molecular oscillations of PER (Nitabach, M. N. *et al.*, 2002). Similarly, Yamaguchi S. *et al.* (2003) have recently shown that TTX distorts synchrony among SCN neurons in an *in vitro* slice and also suppresses clock gene expression.

Calcium entry through voltage-gated Ca^{2+} channels is one likely candidate for transducing membrane electrical events to intracellular gene expression (van den Pol, A. N. and Obrietan, K., 2002). Indeed, blocking Ca^{2+} influx in SCN neurons *in vitro* abolishes the rhythmic expression of *Per1* (Lundkvist, G. B. *et al.*, 2005). However, Ikeda M. *et al.* (2003) reported a TTX-resistant circadian rhythm in cytosolic, but not nuclear Ca^{2+} concentration in SCN neurons transfected with a Ca^{2+}-sensitive fluorescent protein (cameleon). The rhythm in cytosolic Ca^{2+} appeared driven by the release of Ca^{2+} from ryanodine-sensitive Ca^{2+} stores and was also resistant to L-type voltage-gated Ca^{2+} channel blockers, suggesting that Ca^{2+} influx through the plasma membrane was not the primary mechanism responsible for the observed rhythm in cytosolic Ca^{2+} (Ikeda, M. *et al.*, 2003). To account for these conflicting data, Lundkvist G. B. *et al.* (2005) suggest that there may be two rhythmic systems affecting intracellular Ca^{2+} levels: one membrane-related electrical rhythm and one intracellular cytosolic Ca^{2+} rhythm. In either case, it seems as though it may be time to incorporate oscillations of intracellular Ca^{2+} into the cellular model of SCN circadian rhythm generation (Lundkvist, G. B. and Block, G. D., 2005).

1.27.1.3 A Retinohypothalamic Tract Innervates the Suprachiasmatic Nucleus

The visual system has played a prominent role in the study of mammalian circadian rhythms over the years. It was long known that in the absence of retinal efferent projections to the brain (e.g., following bilateral orbital enucleation), rhythmic behavior persists, expressing a free-running circadian period under light/dark conditions as if the eyeless animals were insensitive to the light (Richter, C. P., 1965). Thus, the early search for Johnson's self-regulating clock in mammals focused on structures in the brain that received retinal afferent fibers. However, systematic attempts to ablate all known retinorecipient structures caudal to the optic chiasm failed to generate the free-running circadian rhythms seen after removal of the eyes. This paradox was resolved following the introduction of autoradiography for the localization of anterogradely transported [^{3}H]-amino acids. Using this new tracing technique, two groups provided an unambiguous demonstration of a previously unknown bilateral retinal projection to the anterior hypothalamus terminating in the SCN located just dorsal to the optic chiasm (Hendrickson, A. E. *et al.*, 1972; Moore, R. Y. and Lenn, N. J., 1972). This was soon followed by the important observation that SCN ablation abolished circadian rhythms of drinking, locomotor activity, and hormone release (Moore, R. Y. and Eichler, V. B., 1972; Stephan, F. K. and Zucker, I., 1972). Based on this groundbreaking work, the SCN became the focus of intense investigation to establish its role as a biological clock. The retinal ganglion cells (RGCs) afferent to the SCN were then identified using retrograde tracing techniques, and it was determined that the retinohypothalamic tract (RHT) arose from a class of RGCs with sparsely branching dendrites and with axon collaterals that innervated the thalamic intergeniculate leaflet (IGL) (Pickard, G. E., 1980; 1982; 1985). The RHT has been described in every animal in which it has been investigated including primates and humans (Figure 3), and the RHT is now recognized as a common feature of the vertebrate visual system (Morin, L. P., 1994).

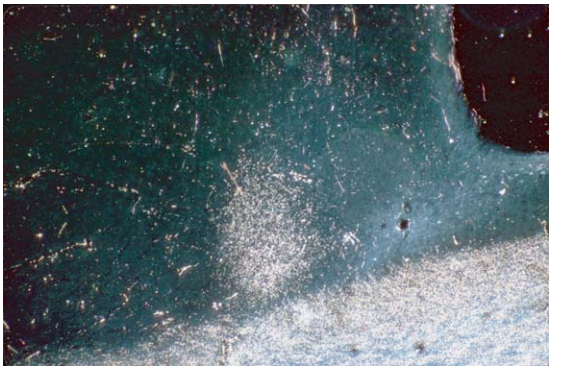

Figure 3 The retinohypothalamic tract (RHT) is a common feature of the mammalian visual system. In this dark-field photomicrograph, RHT processes terminating in the hypothalamic suprachiasmatic nucleus were labeled by a horseradish peroxidase (HRP) injection into the vitreous chamber of one eye of a pig-tailed macaque (*Macaca nemestrina*). The oval-shaped RHT terminal field is evident just above the optic chiasm near the midline, and just lateral to the third ventricle evident in the upper right of the photomicrograph. HRP anterograde tracing procedures were similar to those described by Pickard G. E. (1982).

1.27.1.4 The Retinohypothalamic Tract Arises from Intrinsically Photosensitive Ganglion Cells that Express Melanopsin

While it was evident from early studies that the RHT conveyed irradiance information to the SCN, it was not clear which retinal neurons relayed signals to the ganglion cells that gave rise to the RHT. It was reported that in mice with severe retinal degeneration caused by the *rd* gene, neither rods nor cones were required for entrainment of circadian behavior to the light/dark cycle, and the possibility was raised that cells other than rods or cones might be sensitive to light (Ebihara, S. and Tsuji, K., 1980; Foster, R. G. *et al.*, 1991). However, because some cone perikarya lacking outer segments but remaining immunoreactive for cone-opsin persist even in quite aged *rd/rd* mice, the possibility of RGCs being directly light sensitive was widely discounted. Foster and colleagues provided more definitive evidence that other retinal neurons may be light sensitive by using transgene constructs that eliminated virtually all rods and cones; the rodless/coneless mice remained capable of entraining their SCN circadian oscillator to the environmental day/night cycle (Freedman, M. S. *et al.*, 1999). Around this time, melanopsin was discovered, a novel mammalian opsin which localized to the inner retina (Provencio, I. *et al.*, 1998; 2000; Chapter Contributions of Horizontal Cells). Berson and co-workers ended the debate with their unambiguous demonstration that SCN-projecting RGCs were intrinsically photosensitive and expressed melanopsin (Berson, D. M. *et al.*, 2002; Hattar, S. *et al.*, 2002). The SCN is densely innervated by melanopsin RGCs (Hattar, S. *et al.*, 2002), and mice lacking rods, cones, and melanopsin fail to entrain to light/dark cycles, making it unlikely that additional opsins contribute to the entrainment process (Hattar, S. *et al.*, 2003; Panda, S. *et al.*, 2003).

It should be noted, however, that a small population (≈10–20%) of SCN-projecting RGCs in rodents do not appear to express melanopsin mRNA (rat; Gooley, J. J. *et al.*, 2003), nor melanopsin protein (golden hamster; Morin, L. P. *et al.*, 2003; Sollars, P. J. *et al.*, 2003). In genetically modified mice in which the *tau-lacZ* gene replaced the melanopsin gene *opn4* (Hattar, S. *et al.*, 2002), some retinal fibers and terminals in the SCN lack the reporter enzyme and thus would appear to arise from nonmelanopsin RGCs (Hattar, S. *et al.*, 2006). Little is currently known regarding the nonmelanopsin RGCs that send afferent fibers to the SCN. It was suggested early on, based on an analysis of the soma size of SCN-projecting RGCs in the golden hamster, that a large majority of RGCs afferent to the SCN had a soma size of about 100 μm^2, whereas an additional very small population of SCN-projecting RGCs was considerably larger (Pickard, G. E., 1982). The functional significance of two populations of RGC afferent to the SCN is unknown, and it remains to be determined whether individual SCN neurons receive input from both melanopsin and conventional RGCs or whether the input from each type of ganglion cell is segregated to specific SCN neurons.

Melanopsin-expressing RGCs are intrinsically photosensitive, yet their dendrites extend into the inner plexiform layer of the retina similar to conventional RGCs. Anatomical and physiological data indicate that rod and/or cone photoreceptors provide input to melanopsin RGCs. Ultrastructural work has shown that the somas and proximal dendrites of melanopsin RGCs located in the ganglion cell layer are postsynaptic to terminals containing ribbon synapses, indicating input from cone bipolar cells. Melanopsin ganglion cell dendrites receive GABAergic and non-GABAergic amacrine cell synapses along their entire length and also in S1 of the inner plexiform layer where most of the dendrites stratify (Belenky, M. A. *et al.*, 2003; Belenky, M. A. and Pickard, G. E., unpublished observations). Recordings from SCN-projecting RGCs in retinas maintained *in vitro* have shown that light can trigger synaptic currents in these cells via activation of ionotropic glutamate and GABA receptors (Perez-Leon, J. A. *et al.*, 2006). In addition, glutamate stimulates a rise in intracellular Ca^{2+} in isolated melanopsin RGCs maintained *in vitro*, and this effect is blocked by ionotropic glutamate receptor antagonists, providing an unambiguous demonstration of the presence of glutamate receptors on these cells (Hartwick, A. T. E., Sollars, P. J., and Pickard, G. E., unpublished observations). How the much faster rod/cone driven signals are integrated with the slow intrinsic light response in SCN-projecting melanopsin RGCs remains to be determined. Taken together, these data make it clear that the retinal circuits that provide irradiance signals to the SCN circadian oscillator are exceptionally complex.

1.27.2 Photic Entrainment of the Suprachiasmatic Nucleus

In mammals, unlike most other animals, retinal light perception and retinal efferent projections to the SCN have been shown to be required for photic

entrainment of circadian rhythms (Nelson, R. J. and Zucker, I., 1981). Campbell S. S. and Murphy P. J. (1998) challenged this long-established view when they reported that extraocular light stimulation (i.e., light on the back of the knee) shifts circadian rhythms of core body temperature and melatonin secretion in humans. Since that report, numerous studies have all failed to confirm extraocular effects of light on circadian rhythms in humans or other mammals (Lockley, S. W. *et al.*, 1998; Yamazaki, S. *et al.*, 1999; Eastman, C. I. *et al.*, 2000; Lushington, K. *et al.*, 2002; Wright, K. P. and Czeisler, C. A., 2002; Rüger, M. *et al.*, 2003). Based on the overwhelming evidence, it must be concluded that the effects of light on the SCN circadian oscillator in mammals require ocular light perception.

1.27.2.1 Two Models of Photic Entrainment: Nonparametric versus Parametric

Simply stated, entrainment of the SCN circadian oscillator to the day/night cycle means that the period of the endogenous SCN circadian oscillation becomes equal to that of the light/dark cycle (see below). Two different models have been proposed to explain the mechanisms by which the SCN circadian clock entrains to the day/night cycle, and these models refer to the nature of the action of light, whether discrete or phasic in the case of nonparametric entrainment, or continuous or tonic in the case of parametric entrainment (Daan, S., 1977). Large phase shifts in circadian behavior evoked by brief light pulses administered to animals in the dark provide the evidence for a nonparametric mechanism. The nonparametric model of entrainment therefore emphasizes instantaneous phase shifts (that reset the clock every day) evoked by light exposure at the dusk and/or dawn transitions of the day/night cycle. Changes in circadian period resulting from exposure to different constant light intensities provide evidence of tonic effects of light on the circadian pacemaker. Thus, the parametric model emphasizes gradual changes in circadian period during daylight exposure.

1.27.2.1.1 Nonparametric entrainment

The nonparametric model of entrainment has been derived primarily from the study of nocturnal rodents, although a similar phase-resetting mechanism exists in diurnal animals including humans. This model proposes that entrainment to the day/night cycle is accomplished by a daily resetting of the SCN such that the light-induced phase shift is equal in magnitude to the difference between the free-running period of the endogenous SCN oscillation and the period of the day/night cycle (i.e., typically 24 h but not restricted to this period). This mechanism is described empirically by the response of animals free-running under constant dark (DD) conditions and exposed briefly to light at different phases of the circadian cycle. The response of the SCN to brief light pulses is phase dependent: light exposure during the subjective day (i.e., the times when the animal would normally be exposed to daylight) has no effect on the phase of the free-running circadian rhythm. In contrast, light exposure early in the subjective night produces phase delays in circadian rhythms, whereas light exposure late in the subjective night results in phase advances. The phase response curve (PRC) to brief light pulses plots the amplitude of the phase shift as a function of the phase of the rhythm at the time of the light stimulation with the onset of wheel-running activity arbitrarily defined as circadian time (CT) 12 (Figure 4).

For nocturnal rodents, the PRC to light very accurately predicts the details of entrainment for short light pulses recurring once every 24 h (Pittendrigh, C. S. and Daan, S., 1976a). These pulses can be as brief as 1 s and as dim as 0.05 lux (DeCoursey, P. J., 1972; Earnest, D. J. and Turek, F. W., 1983). Circadian entrainment by the widely accepted nonparametric model of entrainment based on the PRC to light is critically dependent on phase shifts occurring at dusk and/or dawn as the portion of the circadian day sensitive to light is coincident with the twilight transitions in the day/night cycle.

1.27.2.1.2 Parametric entrainment

The discrete or nonparametric model of entrainment based on the PRC to brief light pulses is insufficient to predict circadian entrainment under all lighting conditions (Pittendrigh, C. S. and Daan, S., 1976b). Moreover, the SCN oscillator can be entrained to continuous dim light that rhythmically varies in intensity from 5 to 10 lux (with peak emission at 510 nm held constant) in the form of a sine wave with a 24 h period (Pickard, G. E., 1989). It is also well documented that the period of the free-running circadian activity rhythm of animals maintained under constant light conditions changes as a function of light intensity (Aschoff, J., 1960). The parametric model of entrainment, also called continuous or tonic, has been proposed to explain these types of observations. In its simplest form, this model states

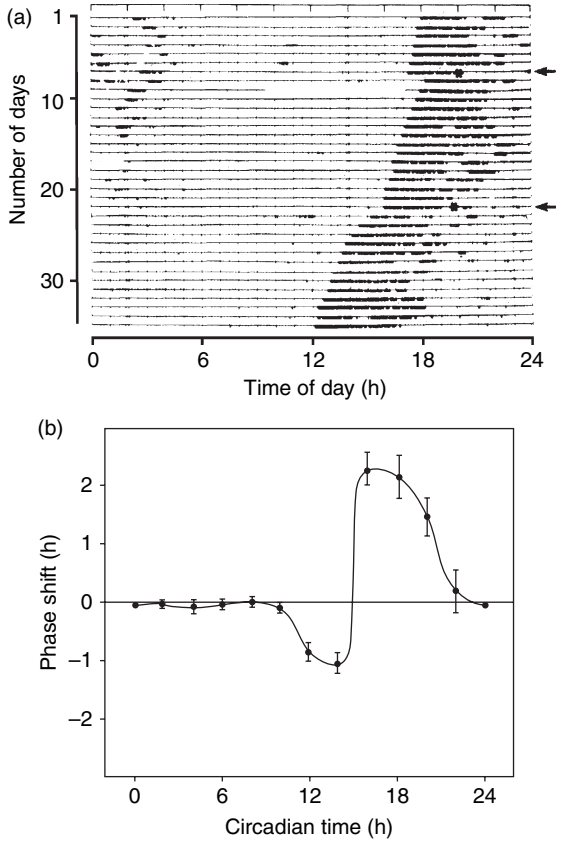

Figure 4 Effect of brief light pulses on the circadian rhythm of wheel-running activity of the golden hamster. (a) Wheel-running activity record of a hamster free-running in constant darkness illustrating the effect of exposure to 15 min of light on the days indicated by arrows and at the times indicated by asterisks. The first light pulse generated a phase delay and the second light pulse a phase advance in the onset of wheel-running activity. (b) A phase response curve to light showing the effects of light pulses presented at various times relative to hamster wheel-running onset defined as circadian time (CT) 12. Phase advances are plotted as positive and phase delays as negative phase shifts ($n = 6 \pm$ SD/time point). (a) Reproduced from Springer and J. Comp. Physiol, Vol. 106, 1976, pp. 253–266, A functional analysis of circadian pacemakers in nocturnal rodents. II. The variability of phase response curves, Daan, S. and Pittendrigh, C. S., with kind permission from Springer Science and Business Media. Reproduced from Takahashi, J. S. and Zatz, M. 1982. Regulation of circadian rhythmicity. *Science* 217, 1104–1111. Reprinted with permission from AAAS.

that the angular velocity or rate of motion of the clock mechanism changes proportionally to the intensity of light present. Thus, this model predicts that under entrainment to a light/dark cycle, the clock runs faster in light and slower in darkness. The modulation of angular velocity under the light and dark portions of the daily cycle would allow the SCN clock to continuously adjust its cycle length to that of the environment.

The ability of light to effect the period of the SCN circadian oscillator directly is perhaps most clearly demonstrated following entrainment to non-24 light/dark cycles and is observed as long-lasting after-effects on circadian period (Pittendrigh, C. S. and Daan, S., 1976a). For example, animals entrained to a 22 h light/dark cycle and then released to free-run in constant darkness initially have free-running periods only slightly greater than 22 h, and only after many (50–100) cycles in DD, does the free-running circadian period approach the endogenous circadian period of the SCN oscillator (Sollars, P. J. *et al.*, 2006a).

1.27.2.1.3 Entrainment in nature

Entrainment under natural photic conditions is likely based on both the nonparametric and the parametric effects of light on the SCN oscillator (Roenneberg, T. *et al.*, 2003), and of course under natural conditions, the exposure to light is quite different in day-active and night-active species. Observations of bats emerging from their caves support the nonparametric model of entrainment under natural conditions as the emergence time follows the time of sunset with a correlation to a narrow range of light intensities throughout the year (DeCoursey, G. and DeCoursey, P. J., 1964). In addition, observations of flying squirrels with access to dark nest boxes have shown that these nocturnal animals sample light at the dusk transition to entrain their SCN circadian system to the light/dark cycle (DeCoursey, P. J., 1986). Night-active golden hamsters living in a seminatural habitat containing a simulated burrow system entrain to the light/dark cycle but are exposed to light for very short amounts of time each day (Pratt, B. L. and Goldman, B. D., 1986). Thus, these limited data suggest that nocturnal animals under natural conditions experience very little light each day but that light at the dusk and dawn transitions is used for entrainment to the day/night cycle presumably via the nonparametric entrainment mechanism. Conversely, in a very carefully conducted field study in which the light environment for individual animals was measured with light-sensitive radio collar transmitters, Hut R. A. *et al.* (1999) reported that diurnal burrow-dwelling European ground squirrels observed under natural conditions never were above ground during twilight at dawn or at dusk. Thus, the animals were never

exposed to light during the portion of the circadian cycle (i.e., subjective night) when light phase shifts the SCN circadian oscillator (via the nonparametric mechanism). Yet these animals entrained to the day/night cycle, presumably in this case, via a continuous or parametric mechanism.

Although both nonparametric and parametric mechanisms may be used for entrainment, nocturnal animals may rely primarily on the dusk/dawn transitions to reset their circadian clocks each day (nonparametric effects), whereas burrow-dwelling diurnal animals appear to use only the parametric mechanism. For animals exposed to complete photoperiods (i.e., non-burrow-dwelling day-active animals), circadian entrainment is probably a combination of parametric and nonparametric mechanisms: by monitoring changes in ambient irradiance over the course of the day, the parametric mechanism would set the period of the endogenous pacemaker close to the 24 h period of the environmental day/night cycle while light at the dusk/dawn transitions coincident with early and/or late subjective night would also generate small daily phase shifts of the SCN circadian clock each day to fine-tune the period even more closely to 24 h.

The nonparametric model of entrainment has been used extensively to probe the cellular and molecular bases of the effects of light on the SCN primarily because the light stimulus and the behavioral responses are easily quantified and correlated with the cellular responses (see below). On the other hand, there is virtually nothing known regarding the cellular or molecular mechanisms underlying the parametric effect of light on the SCN because no convenient metric exists to analyze the modulation of the angular velocity of the SCN circadian oscillator.

It is interesting to speculate whether the two different entrainment mechanisms might be related to the two different populations of RGCs projecting to the SCN. The very sluggish irradiance-dependent responses of melanopsin RGCs to light may be better tuned to gradual changes in environmental lighting conditions, whereas the rod/cone input to the non-melanopsin SCN-projecting RGCs would seem better equipped to transmit signals elicited by short-duration light exposure. Considering the very slow response kinetics of melanopsin RGCs to light (Berson, D. M. *et al.*, 2002), it seems unlikely that these cells could contribute significantly to retinal input to the SCN during entrainment to daily 1 s light pulses. However, both the nonparametric (light-induced phase shifts) and the parametric (lengthening of circadian period in constant light) effects of light on the SCN circadian system are attenuated in melanopsin-knockout mice (Panda, S. *et al.*, 2002; Ruby, N. F. *et al.*, 2002).

1.27.2.2 Entrainment Confers Clock-Like Properties to the Suprachiasmatic Nucleus

The SCN circadian oscillator derives functional utility from its ability to be entrained to the 24 h environmental day/night cycle via input from the retina irrespective of whether a nonparametric or parametric mechanism is used. Entrainment provides a predictable and appropriate phase relationship to the day/night cycle, in effect enabling recognition of local time. The SCN circadian oscillator is thus said to function as a biological clock (Pittendrigh, C. S. and Daan, S., 1976b). Entrainment differs from simple synchronization to changes in the light/dark cycle. Entrainment is neither passive nor driven and therefore allows for great plasticity and adaptive potential. This plasticity is evidenced, for example, by the change in the phase angle of entrainment in the golden hamster that occurs with seasonal changes in day length (Elliott, J. A., 1976). Seasonal inversions of activity patterns have been described in normally nocturnal bats that become diurnal in the winter due to the availability of insects (Daan, S., 1981). Another example of plasticity in entrainment is the temporal partitioning that exists between two species of spiny mouse (*Acomys*). When coexisting in nature, the common spiny mouse (*Acomys cahirinus*) is nocturnal, whereas the golden spiny mouse (*Acomys russatus*) is diurnal. When the common spiny mouse is removed from the shared habitat, the golden spiny mouse becomes nocturnal; chemical signals released by *A. cahirinus* may alter the entrainment of *A. russatus* to the day/night cycle (Haim, A. and Rozenfeld, F. M., 1993; Shargal, E. *et al.*, 2000).

The establishment of an appropriate phase relationship between the environment and the circadian system allows the SCN to generate a temporal program whereby biological functions occur at specific times within the day/night cycle (Hastings, M. H. *et al.*, 2003). Alterations in SCN circadian function resulting from changes in the response of the SCN to RHT input or changes in SCN gene activity can result in altered phase relationships of daily oscillations in physiology, metabolism, or behavior with the day/night cycle. Such alterations in circadian function and the accompanying changes in phase have been associated with human disorders. Individuals

suffering from annual recurring depression or seasonal affective disorder (SAD) typically have phase-delayed circadian rhythms (Lewy, A. J. *et al.*, 1987); appropriately timed treatment with light can correct the alteration in phase and alleviate the depressive symptoms (Terman, M. and Terman, J. S., 2005). Individuals with advanced sleep phase syndrome (ASPS) regularly fall asleep in the early evening, whereas people with delayed sleep phase syndrome (DSPS) typically cannot fall asleep until early morning. These individuals may have an abnormality in one of the *Per* genes, resulting in an altered circadian period and hence an altered phase angle of entrainment of the sleep–wake cycle (Jones, C. R. *et al.*, 1999; Ebisawa, T. *et al.*, 2001; Toh, K. L. *et al.*, 2001; Archer, S. N. *et al.*, 2003).

1.27.2.3 Suprachiasmatic Nucleus Gating of the Light Response

Illumination of the retina evokes excitatory postsynaptic currents (EPSCs) in a subpopulation of SCN neurons. These responses have long latencies and are sustained (Meijer, J. H. and Schwartz, W. J., 2003), similar to the responses of ipRGCs to light (Berson, D. M., 2003). The light-induced EPSCs are the result of glutamate release from the RHT and are mediated by both ionotropic and metabotropic glutamate receptors. The location of light-responsive neurons in the SCN corresponds to the terminal field of the RHT primarily within the ventral and lateral aspects of the SCN, although species differences in the RHT terminal field exist and RHT fibers can be found throughout almost all of the SCN in many species (Hattar, S. *et al.*, 2006; Morin, L. P. and Allen, C. N., 2006). The excitatory response to NMDA is larger during the night than during the day, whereas AMPA/kainate-induced currents do not show a day/night difference (Pennartz, C. M. *et al.*, 2001; Michel, S. *et al.*, 2002). In addition to glutamate, most (if not all) SCN-projecting RGCs also synthesize pituitary adenylate cyclase-activating polypeptide (PACAP), which may act as a modulator of the glutamatergic input to the SCN (Hannibal, J., 2006).

Several reports from Obrietan and colleagues have provided evidence that the p42/p44 mitogen-activated protein kinase (MAPK) signal transduction pathway plays an important role in gating the responsiveness of the SCN to light. The MAPK pathway in the SCN is induced by light in a phase-restricted manner, couples light to transcriptional activation, and mediates light-induced phase shifts (Obrietan, K. *et al.*, 1998; Butcher, G. Q. *et al.*, 2002; Coogan, A. N. and Piggins, H. D., 2003; Dziema, H. *et al.*, 2003). MAPK activation is also triggered by glutamate and PACAP (Butcher, G. Q. *et al.*, 2005). The Ras-like G-protein Dexras1 also appears to be a critical factor in this process. *Dexras1*-null mice exhibit a restructured PRC to light at night and a loss of gating to photic resetting during the subjective day (Cheng, H.-Y. M. *et al.*, 2006). The exact mechanisms by which the SCN clock gates its response to light, shifting its phase during the subjective night but not during the subjective day, remain to be fully elucidated.

Investigation into the genes that might be involved in light-induced pacemaker resetting was initiated by the seminal observation that light induces a rapid and transient expression of the transcription factor c-Fos within the SCN during the same phases of the day/night cycle that light shifts the SCN circadian oscillation (Rea, M. A., 1989; Kornhauser, J. M. *et al.*, 1990). The *Per* genes (*Per1* and *Per2*) in the SCN are photoinducible with a phase dependence similar to that of light-induced behavioral phase shifts (Albrecht, U. *et al.*, 1997; Shigeyoshi, Y. *et al.*, 1997). Daan S. *et al.* (2001) offered an intriguing two-component molecular model for light-induced phase shifting in the SCN inspired by earlier work suggesting that *mPer1*-mediated phase advances and *mPer2* phase delays. However, a subsequent analysis of phase shift responses to light in mice lacking functional *Per* (*mPer1* and *mPer2*) or *Cry* (*mCry1* and *mCry2*) genes by Daan and co-workers revealed that all four genotypes of mice retain the capacity for both advancing and delaying responses to light, suggesting that neither *Per* nor *Cry* genes are associated specifically with light-induced phase advances or delays (Spoelstra, K. *et al.*, 2004). Thus, the molecular mechanisms underlying the biphasic response of the SCN to light remain to be determined.

1.27.3 Serotonergic Modulation of Photic Input to the Suprachiasmatic Nucleus

The SCN receives a robust serotonergic input arising from ascending projections of serotonin (5-HT) neurons in the mesencephalic median raphe nucleus. In an attempt to address the role of this dense monoaminergic projection to the SCN, it was determined early on that a 5-HT input to the SCN is not required for the generation of circadian activity rhythms (Block, M. and Zucker, I., 1976). This

finding resonates with the general theme outlined much later by Jacobs B. L. and Azmitia E. C. (1992) that 5-HT neurons do not play an essential role in physiological and behavioral processes but rather exert tonic modulatory influences on their targets. Since a substantial overlap exists between the distributions of the RHT and 5-HT terminal fields in the SCN, a modulatory influence of 5-HT on RHT input to the SCN was sought. Morin and colleagues were the first to demonstrate a modulatory role of 5-HT in the SCN; depletion of 5-HT within the SCN produced a small but significant change in the phase angle of entrainment of the circadian activity rhythm to the light/dark cycle and an augmentation of light-induced phase shifts, suggesting a tonic inhibitory influence of 5-HT on SCN responses to light (Smale, L. *et al.*, 1990; Morin, L. P. and Blanchard, J. H., 1991). However, at that time neither the 5-HT receptor subtype(s) mediating these effects nor their subcellular location within the SCN was known.

1.27.3.1 5-HT_{1B} Receptor-Mediated Inhibition of Retinohypothalamic Tract Input to the Suprachiasmatic Nucleus

There are at least 14 different 5-HT receptor subtypes grouped into several families, and as many as six 5-HT receptor subtypes have been described in the SCN including the 5-HT_{1A}, 5-HT_{1B}, 5-HT_{2A}, 5-HT_{2C}, 5-HT_{5A}, and 5-HT_7 (Belenky, M. A. and Pickard, G. E., 2001). Of these 5-HT receptor subtypes, activation of 5-HT_{1B} and 5-HT_7 receptors in the SCN attenuates light-induced responses (Morin, L. P., 1999). To date, the best-documented role for 5-HT in the SCN is its ability to modulate SCN sensitivity to light via presynaptic 5-HT_{1B} receptors located on RHT terminals. Bilateral enucleation reduces the number of 5-HT_{1B} binding sites in the SCN (Pickard, G. E. *et al.*, 1996; Manrique, C. *et al.*, 1999), and ultrastructural work has provided direct evidence for 5-HT_{1B} receptors on RHT terminals (Pickard, G. E. *et al.*, 1999). Activation of these presynaptic 5-HT_{1B} receptors *in vivo* attenuates (1) light-induced behavioral phase shifts in rodents (Pickard, G. E. *et al.*, 1996; Pickard, G. E. and Rea, M. A., 1997), (2) light-induced suppression of pineal melatonin (Rea, M. A. and Pickard, G. E., 2000), and (3) light-induced expression of several genes in the SCN (Pickard, G. E. *et al.*, 1996; Hayashi, S. *et al.*, 2001; Shimazoe, T. *et al.*, 2004). Moreover, 5-HT_{1B} receptor agonists applied to the SCN *in vitro* inhibit optic nerve-evoked glutamatergic EPSCs (Pickard, G. E. *et al.*, 1999; Smith, B. N. *et al.*, 2001), and these responses are eliminated in mice lacking functional 5-HT_{1B} receptors (Smith, B. N. *et al.*, 2001).

Based on substantial experimental evidence indicating that activation of 5-HT_{1B} presynaptic receptors on RHT terminals produces an inhibitory effect on RHT glutamate release and a subsequent reduction in photic input to the SCN, it might have been predicted that the circadian system of mice lacking functional 5-HT_{1B} receptors would show enhanced responses to light resulting from disinhibition. Indeed, 5-HT_{1B} receptor-knockout (KO) mice exhibit an exaggerated response to constant light treatment as evidenced by a greater lengthening of the free-running period compared with wild-type mice (Sollars, P. J. *et al.*, 2002). However, 5-HT_{1B} receptor-KO mice are actually less sensitive to light; they have reduced light-induced behavioral phase shifts and they show a reduction in light-induced Fos expression in the SCN (Sollars, P. J. *et al.*, 2006a; 2006b). The enhanced response of 5-HT_{1B} receptor-KO mice to constant light is apparently the result of a differential reduction in the effects of light in the early versus the late subjective night (Sollars, P. J. *et al.*, 2006a). Although it is clear that the SCN of 5-HT_{1B} receptor-KO mice has an attenuated response to light, it is not known with certainty why the circadian system responds in such a manner to the lack of 5-HT_{1B} presynaptic receptors. It has been suggested that increased GABAergic transmission in the SCN may contribute to this phenotype as 5-HT_{1B} receptors are also located presynaptically on GABA terminals in the SCN (Bramley, J. R. *et al.*, 2005), and loss of the 5-HT_{1B} receptor-mediated presynaptic inhibition in the 5-HT_{1B} receptor-KO mice could lead to increased GABA release.

Despite the considerable experimental evidence indicating that activation of 5-HT_{1B} presynaptic receptors on RHT terminals modulates photic input to the SCN, the role these receptors play in the entrainment process is only beginning to be understood. Mice lacking functional 5-HT_{1B} receptors entrain normally to standard laboratory 12L:12D conditions (Sollars, P. J. *et al.*, 2006a), but under these environmental lighting conditions, only a small daily light-induced phase delay is required for entrainment based on the nonparametric model of entrainment. When entrainment is examined under non-24-h light/dark cycles (T cycles), 5-HT_{1B}-KO mice show highly significant alterations in their phase angle of

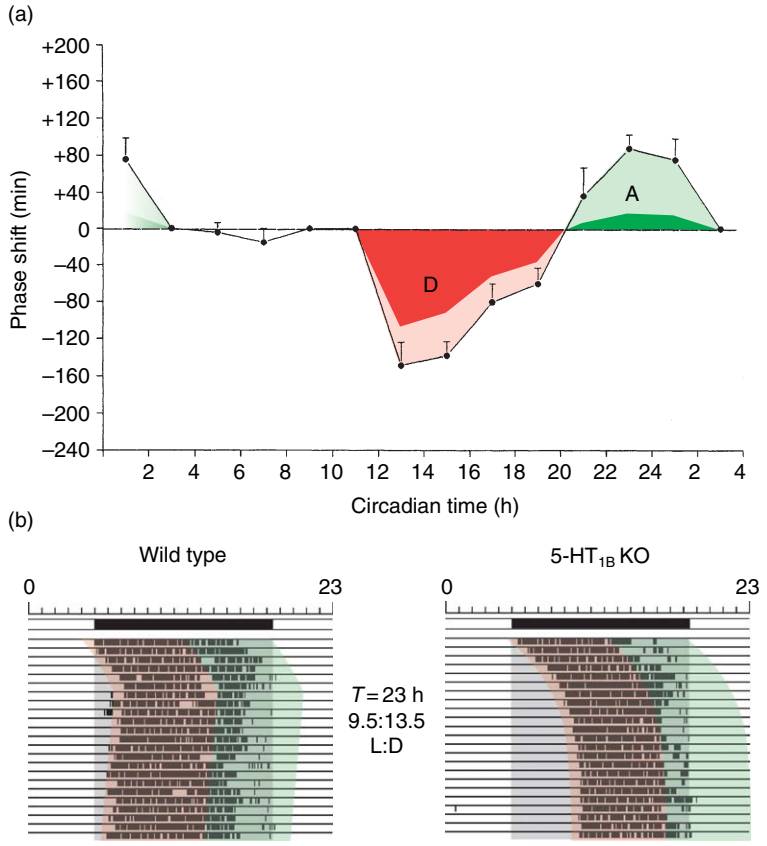

Figure 5 (a) A phase response curve (PRC) to light for a wild-type and a 5-HT_{1B}-knockout (KO) mouse. Wild-type (C57BL/6) mouse data (•—•) are redrawn from Schwartz and Zimmerman (1990) with the phase delay region (D) depicted as light red and the phase advance region (A) shown as light green. Light pulses were administered relative to activity onset designated as circadian time (CT) 12. Superimposed over the wild-type PRC in dark red and dark green is the predicted PRC for 5-HT_{1B} KO mice based on light-induced phase shifts observed at CT 16 and CT 23 from Sollars P. J. *et al.* (2006a). (b) Wheel-running activity records plotted in the standard manner, with each day's activity plotted beneath the previous day's activity, of a wild-type and a 5-HT_{1B}-KO mouse maintained in a 23 h short day light/dark cycle (9.5L:13.5D). Animals had been entrained to 12L:12D before being transferred to the 23-h short-day environment. The phase delay region (red) and phase advance region (green) are superimposed over the wheel-running data to illustrate the relationship between light and the late subjective night that is required for the 5-HT_{1B}-KO mouse entrain to the L:D cycle due to the reduced response of the suprachiasmatic nucleus (SCN) to retinohypothalamic tract (RHT) input. The greatly attenuated response of the 5-HT_{1B}-KO mouse to light in the late subjective night (a) requires that a greater portion of the late subjective night is coincident with the early morning light, resulting in a more delayed phase angle of entrainment (i.e., activity onset relative to lights off). The bar above the activity data and the gray-shaded region indicate the daily 13.5 h dark period. Reproduced from Sollars, P.J., Ogilvie, M.D., Simpson, A.M., and Pickard, G.E. 2006a. Photic entrainment is altered in the 5-HT_{1B} receptor knockout mouse. *J. Biol. Rhythms* 21, 21–32, with permision from SAGE publications.

entrainment, consistent with a reduction in the sensitivity of the SCN circadian system to light (Figure 5). Under short-day (winter-like) conditions, the phase angle of entrainment of 5-HT_{1B}-KO mice is phase delayed (i.e., the onset of wheel-running activity is initiated more than 4 h after lights off; Sollars, P. J. *et al.*, 2006a), similar to the phase-delayed circadian rhythms observed in SAD patients (Terman, M. and Terman, J. S., 2005). Various lines of clinical evidence point to a significant role for 5-HT in the pathophysiology of SAD and alterations in the function of 5-HT_{1B} receptors have been associated with depression-like states (Svenningsson, P. *et al.*, 2006).

1.27.4 Anatomical Organization of the Suprachiasmatic Nucleus

The SCN is composed of a heterogeneous group of about 8–10 000 very small neurons within a complex

neuropil containing a large variety of synapses. The dendritic arbors of SCN neurons are relatively simple with most cells having only two or three dendrites that branch very little. Dendrites in one region of the nucleus often reach into other parts of the SCN and are not always confined to the nucleus; axons enter the nucleus from all directions. Most SCN neurons are GABAergic and possess local collaterals innervating other neurons within the nucleus, thus forming a complex intra-SCN network that is important for the functional coordination of the unitary output of SCN circadian oscillations (van den Pol, A. N., 1991; Strecker, G. J. *et al.*, 1997; Liu, C. and Reppert, S. M., 2000).

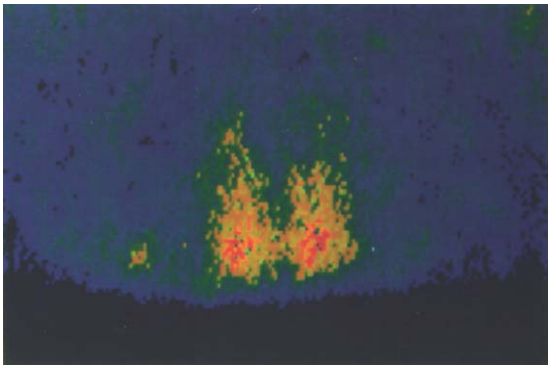
1.27.4.1 Suprachiasmatic Nucleus Divisions

Several different neuroactive peptides have been localized within the SCN. Based primarily on the nonhomogenous distribution of these peptidergic neurons in the SCN, the nucleus can be subdivided into divisions: a ventrolateral region rich in vasoactive intestinal polypeptide (VIP) neurons and a dorsomedial region containing vasopressin (VP) neurons although most if not all of these neurons colocalize with GABA. This simplistic two-division organizational scheme based on chemoarchitecture has been replaced in recent years with the terms core and shell (Moore, R. Y., 1996). The SCN core/shell schema is described as a VIP neuron region that receives dense retinal and 5-HT afferents that is surrounded by a shell region containing VP neurons and receiving afferents from nonvisual cortical and subcortical regions (Moore, R. Y. *et al.*, 2002). In the core/shell organizational plan, RHT input is to the core and the core relays this photic information to the shell. However, Morin and colleagues have indicated that for a variety of reasons the core/shell terminology is problematic (including significant species variation) and perhaps a serious oversimplification of the complex organization of the mammalian SCN (Morin, L. P. and Allen, C. N., 2006; Morin, L. P. *et al.*, 2006; Morin, L. P., 2007). In addition, a one-way serial model of information transfer from a retinorecipient core to a critical locus for light-induced responses in clock cells located in the shell region (Yan, L. and Silver, R., 2002) is inconsistent both with the distribution of retinal fibers seen throughout much of the SCN in several species (Hattar, S. *et al.*, 2006) and with the reciprocal innervation reported between phenotypically defined SCN compartments (Daikoku, S. *et al.*, 1992; Romijn, H. J. *et al.*, 1997).

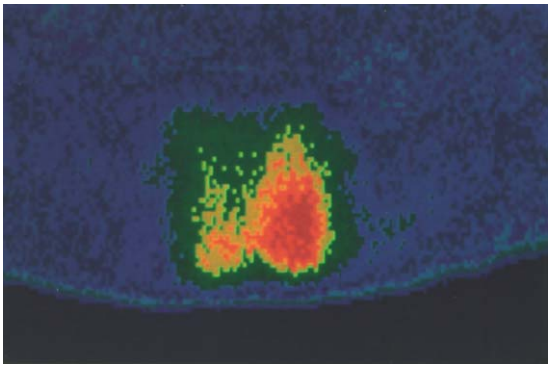
When maintained under cyclic lighting conditions, the left and right SCN function as a unitary circadian pacemaker due to the entraining influence of photic signals reaching each SCN, although a single SCN (right or left) is sufficient to drive circadian behavioral rhythms. In constant dark conditions, anatomical connections between the left and right suprachiasmatic nuclei may help keep the two sides in phase (Pickard, G. E., 1982). However, under conditions of constant light, some animals demonstrate a dissociation of the circadian activity rhythm into two components that initially have different circadian periods until an antiphase relationship is established between the two separate bouts of locomotor activity. This phenomenon is termed splitting, and although it was initially taken to provide the strongest evidence that the mammalian circadian pacemaker must be composed of multiple circadian oscillators, the SCN itself appears to regulate the split activity, with either side regulating one of the two bouts. This was first suggested because unilateral SCN ablation was found to abolish behavioral splitting (Pickard, G. E. and Turek, F. W., 1982). Further evidence consistent with the interpretation that splitting is the result of the oscillations of each SCN operating 180° out of phase was first shown in the asymmetrical distribution of glucose metabolism observed between the two SCN of animals demonstrating split behavioral rhythms (Figure 6) and more recently in the expression of *Per* and *Bmal1* in the two SCN in such animals (de la Iglesia, H. O. *et al.*, 2000).

1.27.4.2 Afferent and Efferent Connections

The best-studied afferent fiber inputs to the SCN are those of RGCs and 5-HT neurons of the median raphe (see above). The SCN also receives a bilateral input from the IGL interposed between the dorsal and the ventral lateral geniculate nuclei. The IGL relays both photic and nonphotic signals to the SCN via the geniculohypothalamic tract (GHT) and is necessary both for the change in free-running period typically seen when animals are maintained under constant lighting conditions (Pickard, G. E. *et al.*, 1987) and for activity-induced phase shifts of the SCN (Harrington, M. E., 1997). The SCN also receives another secondary visual input from the pretectal area. Additional afferents arise from the midline paraventricular nucleus of the thalamus,



CT 14 Nonsplitter



CT 14 Splitter

Figure 6 Autoradiographs of coronal brain sections through the suprachiasmatic nucleus (SCN) of a hamster that showed a single free-running bout of wheel-running activity in constant light (nonsplitter, upper panel) and of a hamster demonstrating a split activity rhythm in constant light (splitter, lower panel), following injection of 2-deoxy-D-[^{14}C] glucose at circadian time (CT) 14 (i.e., 2 h before activity onset). Note the asymmetrical density of label over the SCN in the splitter (Sollars, P. J., 1991).

limbic cortex, basal forebrain, and other hypothalamic nuclei (Moore, R. Y., 2002).

The majority of SCN efferent projections are to sites within the hypothalamus and preoptic area. SCN innervation of the dorsomedial hypothalamic nucleus participates in the regulation of the orexin/hypocretin system, which consolidates wakefulness (Aston-Jones, G. *et al.*, 2001). A major projection of the SCN is to the subparaventricular zone beginning at the caudal border of the SCN and terminating near the ventral border of the paraventricular nucleus of the hypothalamus. SCN projections outside the hypothalamus include a dorsally directed pathway to the bed nucleus of the stria terminalis and the midline paraventricular nucleus of the thalamus that relays SCN signals to the medial prefrontal cortex (Watts, A. G., 1991; Sylvester, C. M. *et al.*, 2002).

Connectivity studies using an alphaherpes virus as a transsynaptic tracer have been conducted with great success in recent years. The attenuated Bartha strain of pseudorabies virus (PRV Bartha) has been particularly useful since it carries a deletion in the unique short region of the genome that removes the coding sequences of several key genes that are required for the virus to spread in an anterograde direction. Thus, PRV Bartha is transported from the site of injection into brain parenchyma or after peripheral application along synaptically linked chains of neurons in only a retrograde direction (Pickard, G. E. *et al.*, 2002). The SCN is transsynaptically labeled after the injection of PRV Bartha into many different peripheral organs, providing evidence that the SCN is linked to a diverse set of sympathetic and parasympathetic motor pathways (Ueyama, T. *et al.*, 1999; Buijs, R. M. *et al.*, 2001; Smeraski, C. A. *et al.*, 2004).

1.27.4.3 Suprachiasmatic Nucleus Regulation of Peripheral Oscillators

Studies in *Drosophila* were once again instrumental in leading the way to a new understanding of the organization of a distributed circadian system. Using a luciferase reporter gene to monitor *Per* expression in isolated tissues maintained in vitro, many autonomous light-sensitive circadian clocks were found throughout the fly's body (Plautz, J. D. *et al.*, 1997). Clock genes are also expressed rhythmically in peripheral tissues in mammals including the liver, lung, and kidney although sustained circadian expression is dependent on signals from the SCN (Akhtar, R. A. *et al.*, 2002). However, it remains to be determined whether the loss of circadian oscillations in peripheral tissues is due to the loss of a driving signal from the SCN necessary to maintain these oscillations or whether it is because the component oscillators in peripheral tissues lose coordination resulting in the loss of temporal definition (Hastings, M. H. *et al.*, 2003). Analyses of circadian oscillations at the single-cell level may resolve this issue.

1.27.5 Summary

Considerable progress has been made in working out the functional organization of the SCN circadian system since Johnson M. S. (1939) first described the clock-like behavior of mice almost three-quarters of a century ago, yet unsurprisingly a considerable amount remains yet to be understood. Continued

rapid advances in molecular biology will continue to elucidate the underpinnings of circadian oscillation generation in the SCN. Further characterization of the retinal circuitry that provides irradiance signals to entrain the SCN oscillator, and the means by which it does so, will be aided both by knockout models and by techniques that isolate the photosensitive RGCs to examine their intrinsic properties. Still to be identified are the several specific pathways by which the SCN informs the rest of the brain and peripheral organs of the temporal structure required for the appropriately synchronous functioning of the whole animal. It is to be hoped that the combined results of these discoveries will ultimately lead to an alleviation of the pathophysiology associated with alterations in SCN circadian function thought to underlie or accompany a wide range of human conditions, both abnormal (as in a host of psychiatric and neurodegenerative diseases) and normal (as in aging, shift-work, and long-distance travel).

1.28.1 Introduction

The two major thalamic nuclei involved in visual processing are the lateral geniculate nucleus and the pulvinar. The lateral geniculate nucleus relays retinal input to the visual cortex, chiefly to the primary visual cortex. The pulvinar innervates most or all visual cortical areas, and what it is relaying has been something of a mystery, although this account makes the case that it is involved chiefly in relaying information between visual areas. Fortunately, most of the details regarding cell and circuit properties are common to thalamic relay nuclei, and so before considering these two visual relay nuclei in detail, it is worth standing back and considering some generally properties of thalamus.

The thalamus is a collection of adjacent nuclei located in the center of the brain. It is a paired structure, each side roughly the size of a walnut. Each of the various nuclei innervates one area of the cortex (unless otherwise specified, cortex use here refers to neocortex) or a small number of adjacent cortical areas. It is important to keep in mind that virtually all information reaching the cortex, and thus attentional and other cognitive levels, must first be relayed by thalamus. Also, as far as we know, every cortical area receives a thalamic projection.

Strictly speaking, thalamus has two broad divisions: dorsal thalamus and ventral thalamus. Dorsal thalamus includes the relay nuclei, namely, the bulk of thalamus in which neurons that project to the cortex are located. These relay nuclei can typically be distinguished by cytoarchitectonic criteria. Generally, homologous nuclei can be discerned across mammals, and so a lateral geniculate nucleus, which relays retinal information to the cortex, is known for all mammalian species so far

studied, but in some cases, identification of homologous nuclei across species remains elusive. The ventral thalamus includes as its chief component the thalamic reticular nucleus, which is a thin shell of neurons that lies generally lateral to the dorsal thalamus, like a shield, extending somewhat dorsally, ventrally, and anteriorly. These reticular cells do not project to the cortex but instead provide a gamma-aminobutyric acid (GABA)ergic, inhibitory input to relay cells of the dorsal thalamus. A minor component of the ventral thalamus is the ventral division of the lateral geniculate nucleus, whose cells project to other brainstem sites but not the cortex; the ventral division of the lateral geniculate nucleus is not considered further. For simplicity in what follows below, unless otherwise indicated, thalamus refers just to the dorsal thalamus, and lateral geniculate nucleus refers just to its dorsal division.

The main thalamic relays of visual information are the lateral geniculate nucleus and pulvinar. (Strictly speaking, this includes the lateral posterior nucleus and is often referred to as the lateral posterior/pulvinar complex, but for the sake of brevity, we shall refer to this simply as the pulvinar.) The main purpose of this chapter is to disabuse readers of the old notions about these thalamic nuclei: namely that the lateral geniculate nucleus is a simple, machine-like relay of retinal information to the primary visual cortex, and the pulvinar is a mysterious entity that innervates extrastriate visual areas and is somehow involved in attention (LaBerge, D. and Buchsbaum, M. S., 1990; Olshausen, B. A. *et al.*, 1993; Anderson, C. H. *et al.*, 2005; Van Essen, D. C., 2005). It is now clear that the complex cell and circuit functions of the thalamus, including the lateral geniculate nucleus, belie any simple relay functions. These thalamic nuclei act as gateways for information flow to the cortex, gateways that are dynamically modulated. Furthermore, we can now seriously consider a relatively new hypothesis for the function of pulvinar as a central element in information transfer between cortical areas involving a corticothalamocortical route. Related to this is the recent appreciation that, as noted above, while all thalamic relays share most basic cell and circuit functions, certain differences between the lateral geniculate nucleus and pulvinar identify them as members of two different kinds of relay found throughout thalamus.

1.28.2 Thalamic Cell Types

The thalamus consists of three basic cell types: relay cells, interneurons, and cells of the thalamic reticular nucleus (for details, see Sherman, S. M. and Guillery, R. W., 1996; 2006). Each of these may be further subdivided, but the complete classification of these cell types has yet to be done. Relay cells are glutamatergic, and the latter two cell types are GABAergic, providing a major inhibitory input to relay cells. Interneurons are located within the main dorsal thalamic relay nuclei, intermixed with relay cells, and the ratio of interneurons to relay cells is roughly 1:3. This ratio is similar throughout thalamus in all mammals with a peculiar exception. That is, outside of the lateral geniculate nucleus, the thalamus of rats and mice are essentially devoid of interneurons, but, curiously, the lateral geniculate nucleus in these animals does have a normal complement of interneurons (Arcelli, P. *et al.*, 1997). This is not a property of rodents, because hamsters, guinea pigs, squirrels, etc., have interneurons throughout thalamus (e.g., Arcelli, P. *et al.*, 1997). However, this point has been questioned recently by evidence that the lateral posterior nucleus of the rat has a substantial fraction of interneurons (Li, J. L. *et al.*, 2003).

1.28.3 Cell Properties

As we learn more about neurons throughout the central nervous system, it is clear that they possess a bewildering variety of voltage-gated ionic membrane conductances, and thalamic relay cells are no exception. The voltage-gated Na^+ conductance underlying the action potential is perhaps the best-known example. Other examples include various voltage-gated K^+ and Ca^{2+} conductances, and a more detailed listing can be found in Sherman S. M. and Guillery R. W. (1996; 2006). The presence of these conductances means that membrane voltage and its temporal pattern, which together determine whether and when each of these becomes activated, play an important role in relay cell excitability and thus the gating of information flow. While most of these conductances are ubiquitous to neurons everywhere, one in particular, a voltage-gated Ca^{2+} conductance that operates via T-type Ca^{2+} channels, is particularly important to relay cell function and relatively specific to thalamic neurons (for details, see Sherman, S. M. and Guillery, R. W., 1996; Sherman, S. M., 2001; Sherman, S. M. and Guillery, R. W., 2006).

1.28.3.1 Properties of T-Type Ca^{2+} Channels

Figure 1 shows the voltage and time dependency for the T channels (Jahnsen, H. and Llinás, R., 1984a; 1984b;

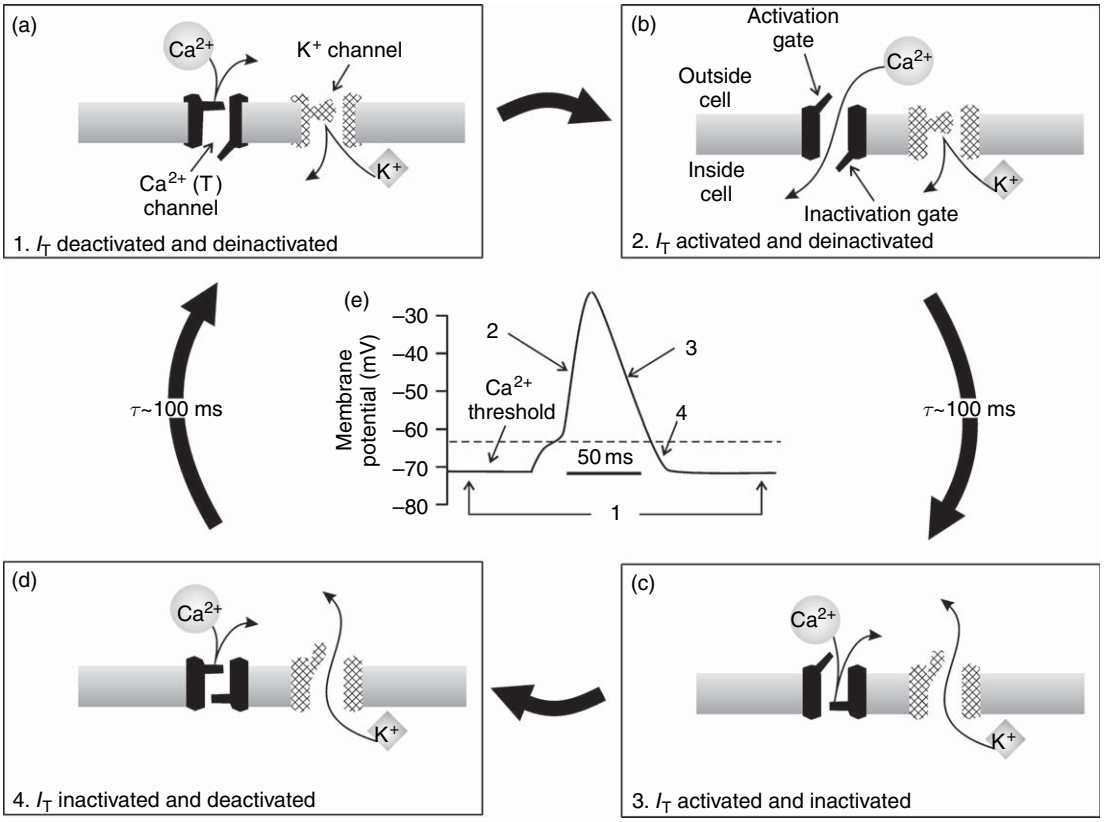

Figure 1 Schematized view of actions of voltage-dependent T (Ca^{2+}) and K^+ channels underlying low-threshold Ca^{2+} spike. Panels (a)–(d) show the sequence of channel events, and the central graph (e) shows the effects on membrane potential. The T channel has two voltage-dependent gates: an activation gate that opens with depolarization and closes at hyperpolarized levels and an inactivation gate that shows the opposite voltage dependency. The K^+ channel shown actually represents several such channels having a single gate that opens during depolarization; thus, these channels do not inactivate. (a) I_T deactivated and deinactivated. At a relatively hyperpolarized resting membrane potential (~70 mV), the activation gate of the T channel is closed, but the inactivation gate is open, and so the T channel is deactivated and deinactivated. The single gate for the K^+ channel is closed. (b) I_T activated and deinactivated. With sufficient depolarization to reach its threshold, the activation gate of the T channel opens, and Ca^{2+} flows into the cell. Thus, the T channel is activated and, for the time being, remains deinactivated. This further depolarizes the cell, providing the rise of the low-threshold spike. (c) I_T activated and inactivated. The inactivation gate of the T channel closes after being depolarized for roughly 100 ms (roughly, because closing of the channel is a complex function of voltage and time), and the K^+ channel also opens. Thus, the continued depolarization inactivates the T channel, although the activation gate remains open. These actions stop the influx of Ca^{2+} and allow the efflux of K^+, serving to repolarize the cell. (d) I_T inactivated and deactivated. Even though the initial resting potential is reached, the T channel remains inactivated, because it takes roughly 100 ms (roughly having the same meaning as above) of hyperpolarization to deinactivate it; thus, the T channel is inactivated and deactivated. It also takes a bit of time for the various K^+ channels to close. Note that the behavior of the T channel is qualitatively exactly like the Na^+ channel involved with the action potential, but with several quantitative differences: the T channel is slower to inactivate and deinactivate, and it operates in a more hyperpolarized regime.

Sherman, S. M., 2001; Sherman, S. M. and Guillery, R. W., 2006). These channels have two voltage gates, because they can be both activated and inactivated by voltage. At rest (roughly −70 mV), the inactivation gate is open, but the activation gate is closed; the channel is thus both deinactivated and deactivated (Figure 1(a)). Following depolarization to threshold for the activation gate (to roughly −65 mV), the activation gate opens and I_T is generated via entry of Ca^{2+} into the cell, leading to the upswing of the all-or-none Ca^{2+} spike; now, the T channel is activated and deinactivated (Figure 1(b)). This Ca^{2+} spike is often termed the low-threshold spike, because its activation threshold is hyperpolarized with respect to that for the action potential. After roughly 100 ms of depolarization, the T channel inactivates (control of the inactivation gate is a complex function of voltage and time (Jahnsen, H. and Llinás, R., 1984a; 1984b; Zhan, H. J. *et al.*, 1999) so that

the more depolarized (or hyperpolarized), the more quickly the gate closes (or opens), but the important point is that under normal conditions, roughly 100 ms is required for these actions) (Figure 1(c)), and this, combined with the activation of a slower series of K^+ conductances, repolarizes the neuron. However, the T channel remains inactivated (Figure 1(d)) for another 100 ms or so, after which time the original state shown in Figure 1(a) is returned. The two gates of the T channel have opposite voltage dependencies, but while the activation gate responds quickly to voltage change, the inactivation gate is slower, requiring roughly 100 ms of polarization change to open or close. Note that the roughly 100 ms of hyperpolarization needed to deinactivate the T channel provides a refractory period, limiting low-threshold Ca^{2+} spiking to 10 Hz.

Note also that this behavior of the T channel is qualitatively identical to that of the Na^+ channel underlying conventional action potentials, although there are two important quantitative differences: the regime of the voltage dependency of the T channel is 5–10 mV more hyperpolarized, and the inactivation kinetics of the T channel are much slower. Also, T channels are not found in the axons. The last point means that it is only action potentials that convey the information relayed to the cortex.

1.28.3.2 Properties of Burst and Tonic Firing

This behavior of T channels underlies the two very different response modes, tonic or burst, that are expressed by thalamic relay cells. How information is relayed to the cortex depends heavily on which response mode is in use (Sherman, S. M. 2001; Swadlow, H. A. and Gusev, A. G., 2001; MacLean, J. N. *et al.*, 2005; Bezdudnaya, T. *et al.*, 2006; Sherman, S. M. and Guillery, R. W., 2006). This is because the same input (e.g., an excitatory postsynaptic potential (EPSP) from retina) will evoke a very different response in the relay cell during tonic versus burst firing (Figures 2(a) and 2(b)). During tonic firing mode, the EPSP directly elicits action potentials, and so a larger EPSP elicits a higher firing rate, forming a fairly linear input/output relationship (Figure 2(c)). However, during bursting, the relationship is highly nonlinear, because the input or EPSP no longer directly elicits action potentials; instead, it elicits the low-threshold spike, which in turn elicits the action potentials, but because the low-threshold

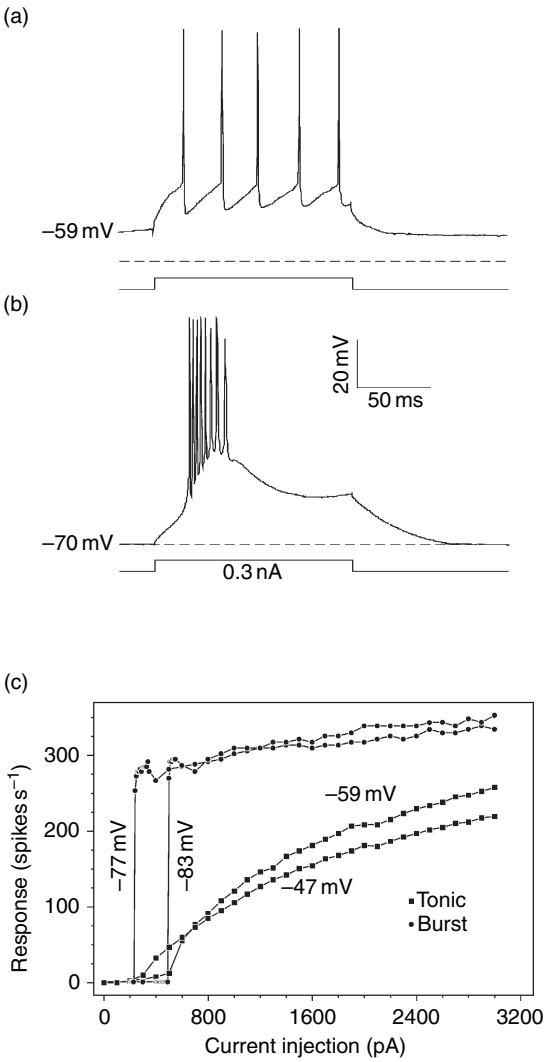

Figure 2 Properties of burst and tonic firing modes for relay cells of the lateral geniculate nucleus of the cat recorded intracellularly *in vitro*. (a, b) Voltage dependency of the low-threshold spike for one cell. Responses are shown to the same depolarizing current pulse administered intracellularly but from two different initial holding potentials. I_T is inactivated with relative depolarization (a), and the response is a succession of unitary action potentials for the duration of the suprathreshold stimulus. This is the *t*onic mode of firing. I_T is deinactivated with relative hyperpolarization (b), and the response is a low-threshold spike with eight action potentials riding its crest. This is the burst mode of firing. (c) Input–output relationship for another cell. The abscissa plots the amplitude of the depolarizing current pulse, and the ordinate plots the evoked firing frequency based on the first six action potentials of the response, since this cell usually exhibited six action potentials per burst in this experiment. The initial holding potentials are shown: −47 and −59 mV reflect tonic mode, whereas −77 and −83 mV reflect burst mode. Redrawn from Sherman, S. M. and Guillery, R. W. 2001. Exploring the Thalamus. Academic Press.

spike is all-or-none, a larger EPSP does not elicit a larger low-threshold spike or a higher firing.

The advantage for tonic firing is pretty clear: if the cortex is to faithfully reproduce the visual scene, the sort of nonlinear distortion seen during burst firing would hamper this process. While less obvious perhaps, there are at least two advantages for burst firing (Sherman, S. M., 2001; Swadlow, A. G. and Gusev, A. G., 2001; MacLean, J. N. *et al.*, 2005; Bezdudnaya, T. *et al.*, 2006; Sherman, S. M. and Guillery, R. W., 2006). First, because burst firing is associated with lower spontaneous activity but the burst itself represents a high rate of firing, burst firing has a higher signal-to-noise ratio and thus better stimulus detectability. Second, burst firing leads to a much greater postsynaptic response in the cortex. The second point follows from the nature of the thalamocortical synapse, which is a depressing synapse: the firing rate during tonic mode is sufficiently high to maintain the synapse in a depressed state, but the silent intervals before each burst (due to the requisite period of hyperpolarization needed to deinactivate I_T) completely relieves the synaptic depression. The overall implication is that, while tonic firing is better for stimulus reconstruction, burst firing is better for the detection of novel stimuli, and associated with this improved detectability is a much stronger cortical response.

1.28.3.3 Hypothesis for Burst and Tonic Firing

These properties of burst and tonic firing have led to the following hypothesis (Sherman, S. M., 2001). To the extent that burst firing is better for stimulus detection, it could be the mode more often seen when the information that the thalamic cell relays is not well attended to (due to drowsiness, attention directed elsewhere, etc.); under these conditions, the burst evoked by a novel stimulus would more likely get through to the cortex and be recognized as a signal than if the cell were firing tonically. In this sense, the burst is a sort of wake-up call that something has changed and that something should be attended to so that its importance can be evaluated. The idea here is not necessarily that bursting provides a stronger overall signal to the cortex than does tonic firing, but rather that bursting overcomes any disadvantage regarding stimulus detectability or cortical activation imposed by inattention. Once the burst activates cortical circuits, the relay cell would then switch to tonic firing so that the novel stimulus can be properly evaluated.

Several recent observations support this hypothesis (Weyand, T. G. *et al.*, 2001; Lesica, N. A. and Stanley, G. B., 2004; Alitto, H. J. *et al.*, 2005; Denning, K. S. and Reinagel, P., 2005). Both tonic and burst firing are seen in awake, behaving animals, including humans, with switching between modes. Bursting is seen relatively rarely in alert animals and more commonly in drowsy animals. Furthermore, recent receptive field studies of the lateral geniculate nucleus show that the type of visual stimulus most likely to evoke a burst is one that switches from inhibition to excitation, such as a dark region covering the receptive field of an on-center cell that is replaced by a bright spot. This indicates that the burst signals a significant change in the form of a novel stimulus just appearing. However, these observations, while supporting the hypothesis, do not constitute proof of its validity. Much more research will be needed to accept or reject the hypothesis.

1.28.4 Circuit Properties

Figure 3 schematically shows the main inputs to thalamic relay cells. The model used here is the lateral

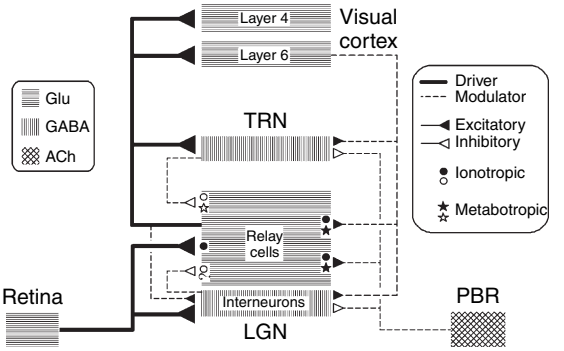

Figure 3 Schematic view of major circuit features of the lateral geniculate nucleus with related receptors present on relay cells. Other thalamic nuclei seem to be organized along the same pattern. The key to the left indicates the major transmitter systems involved. The retinal input activates only ionotropic receptors (circles), whereas all nonretinal inputs activate metabotropic receptors (stars) and often ionotropic receptors as well. The question mark related to input from interneurons indicates uncertainty whether metabotropic receptors are involved. Thick solid and thin dashed lines indicate driver and modulator inputs, respectively. Filled and open icons for synaptic terminals indicate excitatory and inhibitory inputs, respectively. ACh, acetylcholine; GABA, gamma-aminobutyric acid; Glu, glutamate; LGN, lateral geniculate nucleus; PBR, parabrachial region of the brainstem; TRN, thalamic reticular nucleus.

geniculate nucleus, because the circuitry shown here is essentially repeated throughout thalamus. For simplicity, certain pathways are omitted, but some that appear to be differentially distributed between the lateral geniculate nucleus and pulvinar are considered below. For details of these other inputs, see Sherman S. M. and Guillery R. W. (1996; 2006).

1.28.4.1 Anatomical Features

Figure 3 shows that retinal input is one of several to geniculate relay cells. Nonretinal input derives from local GABAergic sources (interneurons and reticular cells), layer 6 of the cortex, which provides a feedback, glutamatergic input, and from the brainstem, mostly from cholinergic cells in a midbrain area known as the parabrachial region. (Another term often applied to this area is pedunculopontine tegmental nucleus. We prefer parabrachial region, because, in many or most species, the cells that innervate thalamus from this area do not have a clear nuclear boundary, and they are found scattered around the brachium conjunctivum.) Thus, the main extrinsic, nonretinal inputs to geniculate relay cells derive from the cortex and brainstem. Note that the local, GABAergic inputs are also innervated by the same cortical and brainstem sources that innervate relay cells. Thus, these extrinsic inputs can affect relay cells directly or indirectly via local GABAergic circuitry.

1.28.4.2 Functional Features

Figure 3 makes clear that, while the retina may provide the main input relayed to the cortex, many nonretinal pathways innervate relay cells, presumably to modulate retinogeniculate transmission. All of these synapses onto relay cells are standard chemical synapses, meaning that they affect relay cells by releasing neurotransmitters that operate through various postsynaptic receptors on the relay cells. These receptors come in two main flavors: ionotropic and metabotropic. Figure 3 shows that a combination of ionotropic and metabotropic receptors is involved in postsynaptic responses of relay cells. Examples of the relevant ionotropic receptors are AMPA and NMDA for glutamate, nicotinic for acetylcholine, and the $GABA_A$ receptor. For metabotropic receptors, examples are various metabotropic glutamate receptors, various muscarinic receptors for acetylcholine, and the $GABA_B$ receptor.

Ionotropic and metabotropic receptors. Differences between ionotropic and metabotropic receptors are many, and only certain ones are considered here (for details, see Nicoll, R. A. *et al.*, 1990; Mott, D. D. and Lewis, D. V., 1994; Pin, J. P. and Duvoisin, R., 1995; Recasens, M. and Vignes, M., 1995; Brown, D. A. *et al.*, 1997; Conn, P. J. and Pin, J. P., 1997). Ionotropic receptors are simpler in construction and function, and the receptor protein itself usually contains the ion channel it controls. Typically, when transmitter binds to the ionotropic receptor, the receptor changes shape, thereby opening the ion channel. This, in turn, allows ions to flow down their electrochemical gradients, leading to an EPSP or IPSP. These ionotropic PSPs typically occurs with brief latencies (<1 ms) and durations (mostly over in 10 or a few tens of milliseconds). Metabotropic receptor functioning is more complicated, because the receptor is linked to ion channels via second messenger systems, which in thalamic relay cells usually involves a G protein and ultimately opens or closes K^+ channels. When K^+ channels open, K^+ flows out of the cell, producing an IPSP, and when K^+ channels close, leakage of K^+ is stopped, leading to an EPSP. One important difference with the activation of ionotropic receptors is that these PSPs related to metabotropic receptors typically have a long latency (~10 ms or so) and duration (hundreds of a millisecond to several seconds).

Figure 3 also shows the pattern of postsynaptic receptors associated with the various inputs onto relay cells. Note that retinal inputs activate only ionotropic receptors (mostly AMPA but also NMDA), whereas all nonretinal inputs activate metabotropic and often also ionotropic receptors. The fast EPSPs activated by retinogeniculate synapses means that for relatively high firing rates in the retinal afferent, it is possible to evoke a single, separate EPSP for each retinal action potential. Put another way, if retinogeniculate synapses activated metabotropic glutamate receptors, the resultant prolonged EPSPs would temporally summate at relatively low firing rates in the afferent; this would act like a low-pass temporal filter, and the result would be a loss of higher-frequency temporal information. Thus, the lack of metabotropic glutamate receptors associated with retinal input maximizes the faithful relay of temporal information. The nonretinal inputs, by activating metabotropic receptors, can achieve sustained changes in membrane potential and thus relay cell excitability, thereby modulating the gain of retinogeniculate transmission.

This pattern of receptors also has implications for the control of firing mode. Recall that to inactivate the T channel (i.e., to close the inactivation gate) requires 100 ms or so of sustained depolarization; likewise, to

deinactivate it (i.e., to open the inactivation gate) requires 100 ms or so of sustained hyperpolarization. This means that the fast EPSPs or inhibitory postsynaptic potentials (IPSPs) seen with ionotropic receptors are ill-suited to affect the inactivation gate; even action potentials, despite their amplitude, are terminated too quickly to effectively inactivate the T channel. In contrast, the sustained postsynaptic potentials of metabotropic receptors are ideally suited to inactivate or deinactivate T channels. It thus follows that retinal input by itself, with its fast EPSPs, is less likely to directly affect T channels. Even evoked action potentials are too fast to have much affect on the inactivation state of these channels.

This seems appropriate in the sense that burst or tonic firing is thought to be largely dependent on behavioral state (Sherman, S. M., 2001), and one would expect that to be mainly the function of the nonretinal inputs to relay cells that do not carry the main information to be relayed. Although visual stimuli can also affect firing rate, this, too, seems to be due to nonretinal afferents. That is, a visual stimulus that inhibits a geniculate cell for a sufficient time (e.g., a dark stimulus falling on the center of an on-center cell) can deinactivate the T channels, and when this stimulus is replaced by an excitatory one (e.g., a bright spot), a burst is evoked (Lesica, N. A. and Stanley, G. B., 2004; Alitto, H. J. *et al.*, 2005; Denning, K. S. and Reinagel, P., 2005). However, this is likely due to inhibitory circuits involving interneurons or reticular cells, or both, and perhaps also involving $GABA_B$ receptors, and is not likely to represent retinal inputs alone. Indeed, evidence exists (reviewed in Sherman, S. M. and Guillery, R. W., 1996; 2006) that metabotropic glutamate receptors activated from layer 6 of the cortex and muscarinic receptors activated from the parabrachial region produce long, slow EPSPs that inactivate the T channels and switch relay cells from burst to tonic firing mode. Likewise, activation of $GABA_B$ receptors from reticular inputs does the opposite: it produces a sustained inhibitory postsynaptic potential that switches firing modes from tonic to burst. Interneurons may also participate in this, but as indicated by the question mark in Figure 3, it is not yet known whether or not these inputs activate $GABA_B$ receptors on relay cells.

Role of parabrachial and cortical inputs. Figure 3 shows that increased activity in parabrachial inputs depolarizes relay cells directly. In addition, increased parabrachial activity inhibits reticular cells and interneurons, thereby disinhibiting relay cells. Thus, increased parabrachial activity results in more depolarized relay cells, which not only makes them more excitable, but also serves to activate their T channels, biasing relay cell responses to tonic mode. This is consistent with evidence that parabrachial neurons become more active and relay cells become less bursty with increasing vigilance, from slow-wave sleep through drowsiness to full attention (Steriade, M. and Contreras, D., 1995; Datta, S. and Siwek, D. F., 2002).

Understanding the consequence of the layer 6 cortical input is much more difficult. Figure 3 suggests that this input directly excites relay cells while it indirectly inhibits them, but in fact, the actual effect of this input depends on details of the circuit that are generally unknown. This is illustrated in Figure 4, which shows two variants of many possible for the relevant circuit. Figure 4(a) shows individual corticogeniculate axons innervating a reticular cell and a relay cell, with the reticular cell innervating the same relay cell. This is an example of feedforward inhibition. The consequence of increased corticogeniculate activity might be little or no net effect on the relay cell's membrane voltage (and T-channel inactivation or deinactivation) if the excitatory and inhibitory inputs are balanced. However, as pointed out by Chance F. S. *et al.* (2002), while this may not affect membrane voltage, the increased synaptic conductance among other factors will reduce relay cell excitability to other (i.e., retinal) inputs; thus, in the lateral geniculate nucleus, activation of this circuit would reduce the gain of retinogeniculate transmission.

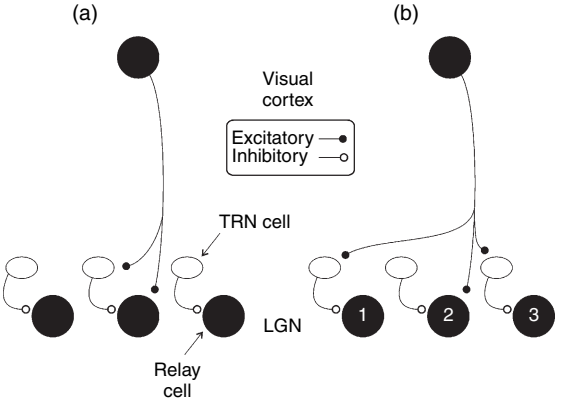

Figure 4 Two patterns among others possible for corticothalamic projection from layer 6 to cells of the thalamic reticular nucleus and geniculate relay cells. (a) Pattern of simple excitation and feedforward inhibition. (b) More complicated pattern in which activation of a cortical axon can excite some relay cells directly and inhibit others through activation of reticular cells. Further details in text. LGN, lateral geniculate nucleus; TRN, thalamic reticular nucleus.

The circuit of Figure 4(b) has very different consequences. Here, activation of the corticogeniculate axon purely excites one or a few relay cells (e.g., cell 2) and purely inhibits others (e.g., cells 1 and 3). Note that this circuit does not involve feedforward inhibition. Also, note that the final effect on relay cell membrane voltage is such that the activation of the corticogeniculate axon would promote tonic firing in cell 2 and burst firing in cells 1 and 3. This means that layer 6 increased corticogeniculate input can have very different and localized effects. Recent evidence is in support of this pattern (Wang, W. *et al.*, 2006). Figure 4 illustrates the importance of a much better understanding of these functional circuits at the single-cell level than we have at present. The example of Figure 4 includes just reticular cells, but one can easily imagine a similar circuit involving interneurons.

1.28.5 The Lateral Geniculate Nucleus

While the above sections describe properties that are applicable to the lateral geniculate nucleus, there are certain features of processing information that are specific to or more readily studied in this nucleus.

1.28.5.1 Parallel Processing

Relay cells in the lateral geniculate nucleus can be divided into at least three functional classes (Sherman, S. M., 1982; Shapley, R. and Lennie, P., 1985; Casagrande, V. A. and Norton, T. T., 1991; Hendry, S. H. C. and Reid, R. C., 2000; Casagrande, V. A. and Xu, X., 2004). Each of these geniculate classes represents a thalamic link in separate streams of retinogeniculocortical processing. That is, there are equivalent distinct classes of retinal ganglion cells that project to the lateral geniculate nucleus, and each retinal class seems to innervate a single class of geniculate relay cell to maintain separate, parallel streams of information to the cortex. In general, the receptive field properties that distinguish these cell types are similar for retina and the lateral geniculate nucleus, because geniculate receptive fields are essentially the same as their retinal inputs. These classes have been best studied in the cat, where they are called X, Y, and W cells, and in the monkey, where they are called parvocellular (P), magnocellular (M), and koniocellular (K). There appears to be a link in homology here between X and P cells, Y and M cells, and W and K cells. Homologies to these parallel cell classes have also been suggested for other species (Casagrande, V. A. and Norton, T. T., 1991; Van Hooser, S. D. *et al.*, 2003; Casagrande, V. A. and Xu, X., 2004).

1.28.5.1.1 The cat lateral geniculate nucleus

X and Y cells. X and Y cells are each a fairly homogeneous class, with both anatomical and receptive field correlates. Anatomically, retinal X cells are known as beta cells and Y cells as alpha cells (Boycott, B. B. and Wässle, H., 1974). Beta cells have smaller cell bodies with smaller dendritic arbors and thinner caliber axons. Similar relationships exist for geniculate X and Y cells (LeVay, S. and Ferster, D., 1977; Friedlander, M. J. *et al.*, 1981). Geniculate X cells have smaller cell bodies with thinner axons, and their dendritic arbors are elongated perpendicular to the geniculate laminar borders (see below for geniculate layers), whereas those of Y cells are organized into a roughly spherical shape. Also, X cells tend to have grape-like appendages near proximal dendritic branch points, whereas Y-cell dendrites are generally smooth. This is interesting, because these appendages on the X cells mark the postsynaptic target of the retinal inputs, whereas on Y cells, retinal inputs terminate directly onto proximal dendritic shafts (Wilson, J. R. *et al.*, 1984; Hamos, J. E. *et al.*, 1986).

The receptive fields of both cell types in retina and the lateral geniculate nucleus are organized into classic center/surround regions. There are roughly equal numbers of on- and off-center cells. However, X cells have smaller receptive fields and respond to higher spatial and lower temporal frequencies (Sherman, S. M., 1982; Shapley, R. and Lennie, P., 1985). These center/surround regions for both X and Y cells exhibit linear summation, but the Y cells, in addition, have small, nonlinear subunits in their receptive fields that produce a doubling response (i.e., a response to both onset and offset to both bright and dark spots) to visual stimuli (Enroth-Cugell, C. and Robson, J. G., 1966; Hochstein, S. and Shapley, R. M., 1976).

Based on receptive field properties, hypotheses have been developed for the distinct function of the X and Y pathways. X cells are thought to provide maximum acuity for detail vision, while Y cells are more important for motion detection and processing of low spatial frequencies (Sherman, S. M., 1985).

W cells. W cells remain a poorly understood cell group and probably represent a heterogeneous group with several distinct classes. However, for convenience and because the final classification and

functional correlates of W cells are lacking, they are considered together here (for further details of these cells, see Sherman, S. M., 1982; Berson, D. M. *et al*., 1998; 1999; Isayama, T. *et al*., 2000). Retinal W cells generally have small to medium-sized cell bodies with long, sparsely branched dendrites, but the morphological features of this group are so varied that any generality must be qualified. W cells so far described in the lateral geniculate nucleus have medium-sized cell bodies and dendritic arbors oriented parallel to the layers (Stanford, L. R. *et al*., 1983). The receptive fields of these cells, both in retina and in the lateral geniculate nucleus, are also quite varied but tend to be large and poorly responsive. Indeed, Cleland B. G. and Levick W. R. (1974) have named them sluggish; some have center/surround configuration, others have poorly defined borders with on/off responses throughout, some have directional selectivity, and some have some wavelength sensitivity. To date, there has not been much speculation regarding the function of the W pathway(s), and this remains a mystery.

1.28.5.1.2 The monkey lateral geniculate nucleus

P and M cells. In the retina (Rodieck, R. W., 1979; Leventhal, A. G. *et al*., 1981), P cells (called midget cells) are smaller than M cells (called parasol cells), and this size differential also holds in the lateral geniculate nucleus, as the names (Parvocellular and Magnocellular) imply. Their receptive fields both in retina and in the lateral geniculate nucleus have the classic center/surround configuration, but P cells have smaller receptive fields (Casagrande, V. A. and Norton, T. T., 1991; Hendry, S. H. C. and Reid, R. C., 2000; Casagrande, V. A. and Xu, X., 2004). M cells are much more sensitive to luminance contrast and moving stimuli, but, while M cells show no wavelength sensitivity, P cells show sensitivity for green and red wavelengths. One exception to this are owl monkeys, which are crepuscular, like cats, and, like cats, are thus not so reliant on color vision. For these animals, P cells show little wavelength sensitivity (O'Keefe, L. P. *et al*., 1998). As is the case for the cat, there has been much speculation concerning the role of these cell types in the monkey. Common suggestions are that P cells are important for color discrimination in monkeys with diurnal behavioral patterns, especially for red/green distinctions, and may also be involved in high acuity vision, whereas M cells provide for better luminance contrast sensitivity and are also important for motion detection (Casagrande, V. A. and Norton, T. T., 1991; Hendry, S. H. C. and Reid, R. C., 2000; Casagrande, V. A. and Xu, X., 2004).

K cells. Like W cells, K cells probably include many distinct cell classes, and also like W cells, are grouped together here, because their complete classification remains to be done. As the name (Koniocellular) implies, these are smaller than M or P cells in both the retina and the lateral geniculate nucleus. Not much is known of their receptive field properties, but some of these cells are thought to be responsible for yellow/blue wavelength discrimination. For a fuller account of K cells, see Martin P. R. *et al*. (1997), Martin P. R. (1998), Silveira L. C. L. *et al*. (1999), and Hendry S. H. C. and Reid R. C. (2000).

1.28.5.2 Laminar Relationships

1.28.5.2.1 Lateral geniculate nucleus

Layering is a constant feature of the lateral geniculate nucleus in all mammals so far studied. In some species (e.g., cats and monkeys), the layering is obvious, because cell-poor interlaminar zones exist to demarcate the layers. In other species (e.g., rats), such zones do not exist, so the layering is less obvious but still present. Each of these layers receives an input from one or the other eye. Geniculate laminar patterns vary greatly among species, but this ocular division between sets of layers seems to be one constant.

In addition to ocular dominance, the various cell types are distributed with varying levels of laminar specificity. In the cat, X and Y cells commingle in the dorsal two layers (called the A layers); the next ventral layer (layer C) has only Y cells; and the ventral few layers have only W cells (Sherman, S. M., 1982). In the rhesus monkey, P and M cells separate into four dorsal parvocellular layers and two ventral magnocellular layers. The K cells not only are found in all the interlaminar zones but also extend into the ventral regions of the parvocellular layers (Casagrande, V. A. and Norton, T. T., 1991; Hendry, S. H. C. and Reid, R. C., 2000; Casagrande, V. A. and Xu, X., 2004). In the mink and ferret, the A layers (containing commingled X and Y cells) further separate into sublayers containing only on- or off-center cells (LeVay, S. and McConnell, S. K., 1982; Stryker, M. P. and Zahs, K. R., 1983), and yet the closely related cat has these on- and off-center cells commingled in single layers. Figure 5 summarizes the laminar patterns for several representative mammalian species to illustrate the sort of bewildering variation present. Geniculate lamination does

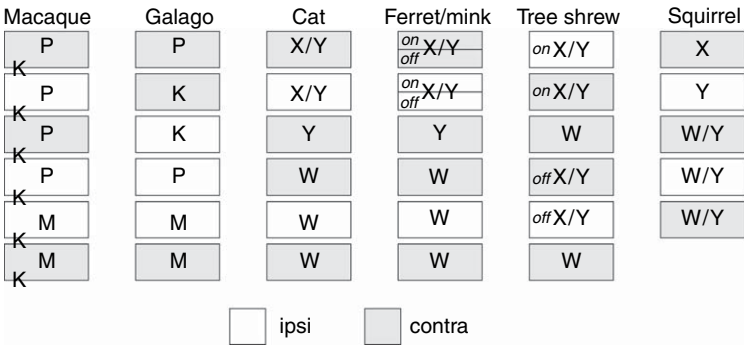

Figure 5 Schematic rendering of layers and distribution of cell types in the lateral geniculate nucleus of six different species (Kaas, J. H. *et al.*, 1972; Sherman, S. M. and Spear, 1982; Sherman, S. M., 1985; Casagrande, V. A. and Norton, T. T., 1991; Hendry, S. H. and Calkins, D. J., 1998; Van Hooser, S. D. *et al.*, 2003). The shaded boxes show layers innervated by the contralateral eye (contra), and the unshaded boxes show the input from the ipsilateral eye (ipsi). The X, Y, and W pathways are shown for the cat, the ferret/mink, the tree shrew, and the squirrel, and the magnocellular (M), parvocellular (P), and koniocellular (K) pathways are shown for the macaque and the galago. Where there is a clear segregation of on- and off-center (*on*, *off*) cells, this is also indicated. From Sherman, S. M. and Guillery, R. W. 2006. Exploring the Thalamus and its Role in Cortical Function, 2nd edn. MIT Press.

correlate with cell type, but the nature and extent of this correlation varies widely across species, and it is difficult to discern any special significance to these correlations.

1.28.5.2.2 Visual cortex

There is also a laminar correlation regarding the target zones of the various cell types (Ferster, D. and LeVay, S., 1978; Blasdel, G. G. and Lund, J. S., 1983; Humphrey, A. L. *et al.*, 1985; Casagrande, V. A. and Xu, X., 2004). In the cat, geniculate X-cell axons innervate the ventral part of layer 4, while those of Y cells innervate the upper part. Geniculate W cells mostly innervate layer 3. A similar arrangement holds for the monkey: P cells innervate the ventral half of layer 4 (sometimes called layer 4Cβ), M cells innervate the dorsal half of layer 4 (sometimes called 4Cα), and K cells mostly innervate layer 3. Thus, through the first stage of processing, the three parallel pathways are kept fairly independent, although what happens further centrally with regard to these pathways is not at all clear.

1.28.6 Drivers and Modulators

Figure 3 illustrates a fundamentally important point that is often overlooked: all inputs to geniculate relay cells are not equal. That is, the retinal input alone represents the main information actually relayed to the cortex. A consideration of receptive field properties helps demonstrate this fact, because the responses of the relay cell to visual stimulation identify the information relayed. It is clear that the receptive fields of geniculate relay cells are remarkably like those of their retinal afferents, having the same center/surround configuration and with only minor, subtle differences (reviewed in Sherman, S. M., 1985). Geniculate receptive fields do not closely match any other extrageniculate afferent: receptive fields of corticogeniculate afferents, which show selectivities for orientation and often direction typical of cortical cells (Gilbert, C. D., 1977), are quite different, and parabrachial inputs are not plausible sources of such clear center/surround properties. If it is the retinal input that provides the information to be relayed, then the nonretinal inputs must have another function. This, plus a number of morphological, pharmacological, and physiological differences that distinguish retinal and nonretinal afferents to relay cells, has led to the idea that these can be functionally divided: the retinal inputs are the drivers (so called because one of their properties is the very strong postsynaptic drive of their target relay cells; see Table 1), while all the nonretinal inputs are the modulators, the idea being that the driver input is the information-bearing input, while the modulators serve to modulate retinogeniculate transmission (Sherman, S. M. and Guillery, R. W., 1998; 2006). Modulation can take many forms, including, for example, the above-mentioned consequences of metabotropic receptor activation that lead to overall

Table 1 Drivers and modulators in lateral geniculate nucleus (LGN) plus layer 5 drivers

Criteria	*Retinal (driver)*	*Layer 5 to higher order (driver)*	*Modulator: layer 6*	*Modulator: PBR*	*Modulator: TRN and Int*
1	Determines relay cell receptive field	Determines relay cell receptive field[a]	Does not determine relay cell receptive field	Does not determine relay cell receptive field	Does not determine relay cell receptive field
2	Activates only ionotropic receptors	Activates only ionotropic receptors	Activates metabotropic receptors	Activates metabotropic receptors	TRN: activates metabotropic receptors; Interneuron: [b]
3	Large EPSPs	Large EPSPs	Small EPSPs	*b*	TRN: small IPSPs; Interneuron: [b]
4	Large terminals on proximal dendrites	Large terminals on proximal dendrites	Small terminals on distal dendrites	Small terminals on proximal dendrites	Small terminals; TRN: distal; Interneuron: proximal
5	Each terminal forms multiple contacts	Each terminal forms multiple contacts	Each terminal forms single contact	Each terminal forms single contact	Each terminal forms single contact
6	Little convergence onto target	Little convergence onto target[a]	Much convergence onto target	*b*	*b*
7	Very few synapses onto relay cells (∼5%)	Very few synapses onto relay cells (∼5%)	Many synapses onto relay cells (∼30%)	Many synapses onto relay cells (∼30%)	Many synapses onto relay cells (∼30%)
8	Often thick axons	Often thick axons	Thin axons	Thin axons	Thin axons
9	Glutamatergic	Glutamatergic	Glutamatergic	Cholinergic	GABAergic
10	Synapses show paired-pulse depression (high *p*)	Synapses show paired-pulse depression (high *p*)[a]	Synapses show paired-pulse facilitation (low *p*)	*b*	*b*
11	Well-localized, dense terminal arbors	Well-localized, dense terminal arbors	Well-localized, dense terminal arbors	Sparse terminal arbors	Well-localized, dense terminal arbors
12	Branches innervate subtelencephalic targets	Branches innervate subtelencephalic targets	Subcortically known to innervate thalamus only	*b*	Subcortically known to innervate thalamus only
13	Innervates dorsal thalamus but not TRN	Innervates dorsal thalamus but not TRN	Innervates dorsal thalamus and TRN	Innervates dorsal thalamus and TRN	TRN: both; Interneuron: dorsal thalamus only

[a]Very limited data to date.
[b]No relevant data available.
EPSP, excitatory postsynaptic potential; PBR, parabrachial region of the brainstem; TRN, thalamic reticular nucleus.

changes in relay cell excitability and that serve to control the tonic/burst transition. In addition, the circuit suggested by Figure 4(a) can operate to control the gain of retinogeniculate transmission.

Many properties distinguish drivers from modulators in thalamus, and the number will likely increase as we learn more about this issue. Table 1, which is not meant to be exhaustive, summarizes some important features (see also Sherman, S. M. and Guillery, R. W., 2006). Layer 5 drivers (the second column in Table 1) are considered below. The 13 criteria in Table 1, in a roughly decreasing order of importance, are as follows:

1. Drivers determine the main receptive field properties of the relay cell; modulators do not.
2. Drivers activate only ionotropic receptors; modulators activate metabotropic receptors as well.
3. Drivers evoke large EPSPs; modulators evoke smaller EPSPs or IPSPs.
4. Drivers form large terminals on proximal dendrites; modulators usually form small terminals throughout the dendritic arbor.
5. Each driver terminal forms multiple large synapses; each modulator terminal usually forms a single, small synapse.
6. Driver inputs show little convergence so that one or a small number of driver axons converge onto the postsynaptic target neuron; where evidence is available, modulator inputs show considerable convergence.
7. Driver inputs produce a small minority (~5%) of the synapses onto thalamic relays cells; many modulator inputs produce larger synaptic numbers (e.g., the cortical and parabrachial modulator inputs in Figure 3 each produces about 30% of the synapses).
8. Drivers have thick axons; modulators have thin axons.
9. Drivers are glutamatergic; modulators can use a variety of neurotransmitters.
10. Driver synapses show high release probability and paired-pulse depression, meaning that a given action potential is likely to result in transmitter release and that, with the initiation of a train of action potentials, there is a period after each evoked postsynaptic potential lasting for tens of a millisecond that the next one will be smaller (depressed); modulator synapses that have been tested so far show the opposite properties of low release probability and paired-pulse facilitation.
11. Driver terminal arbors are well localized with a dense array of terminals; modulator terminal arbors can be either well localized and dense or relatively poorly localized and sparse.
12. Branches of driver axons tend to innervate extrathalamic targets as well as thalamus (e.g., many or all retinogeniculate axons branch and also innervate midbrain targets); those modulator inputs so far tested innervate thalamus only.
13. Driver inputs innervate relay cells and interneurons in dorsal thalamus but do not innervate the thalamic reticular nucleus; modulator inputs innervate relay cells, interneurons, and reticular cells.

This driver/modulator distinction can be applied, not just to the lateral geniculate nucleus, but also to all thalamic relays for which sufficient information is available, such as the ventral portion of the medial geniculate nucleus (the primary auditory thalamic relay) and the ventral posterior nucleus (the primary somatosensory thalamic relay). The main point, again, is that not all anatomical pathways are functionally equivalent, acting in some sort of anatomical democracy, and if one is to understand the functional organization of the thalamus and what it is that is being relayed, one must identify and characterize the driver input. As we shall see, identifying the driver to the lateral geniculate nucleus is clear, but it is not so obvious for the pulvinar. An important possibility raised below is that this driver/modulator distinction may also apply outside of thalamus.

Regarding criterion 7 above, it may seem surprising at first that the main information to be relayed is responsible for such a small minority of synapses onto relay cells, but two factors may help explain this. First, despite the small number of inputs anatomically, these are especially powerful and effectively drive the relay cells. Second, if a relatively small but powerful number of synapses are needed to relay the basic information, many more, individually weaker synapses that can be combined in different ways are needed to provide a wide range of subtle modulatory effects.

One last point needs to be emphasized with respect to geniculate circuitry that should be considered when evaluating any circuits in the central nervous system. With anatomical information alone, such as numbers of synapses from subcortical sites, the number from the parabrachial region (~30%) is considerably greater than that from retina (5–10%). Such anatomical data in isolation might lead one to the mistaken conclusion that the parabrachial input is

the more important and thus represents the information being relayed, while the retinal input, being so small, performs some vague, lesser function that might not even merit inclusion in some schematic illustrations of geniculate circuitry. The key lesson here is that anatomical data, on their own, can be very misleading when trying to unravel functional circuits. With regard to information processing through thalamus, a most important issue is to identify what is being relayed, and to do so, it is potentially misleading to treat all pathways as equal: one must instead separately identify drivers from modulators. Look through any textbook on neuroscience, and perhaps even this volume, and you are likely to find examples of schematically illustrated circuits that are based on anatomy alone, as if all inputs were drivers in the sense the term has been used here. If the concept of drivers and modulators has validity beyond thalamus, many of these suggested circuits need to be reconsidered.

1.28.7 First- and Higher-Order Relays: The Lateral Geniculate Nucleus and Pulvinar

There are two ways to think about the function of the thalamus. One is to consider the properties of thalamic circuitry as they affect relay functions. For one example, how do the modulators affect retinogeniculate transmission? The other is to consider what it is that a thalamic nucleus is actually relaying. Put another way, we can define the function of lateral geniculate nucleus or the ventral posterior nucleus as relaying retinal or medial lemniscal information, respectfully. It is this latter aspect of thalamic functioning, which really boils down to identifying the driver input, that chiefly concerns us in this section.

1.28.7.1 Layer 5 Corticothalamic Inputs as Drivers

Identifying the function of a thalamic nucleus by identifying the driver input may seem obvious and trivial for well-studied relays like the lateral geniculate nucleus, but there are many other less-well-understood relays with unknown functions because, until recently, their driver inputs were undefined. Examples are the pulvinar and medial dorsal nucleus. We now know that a major source of driver input to thalamic relays like these is layer 5 of the cortex. This is illustrated in Figure 6.

First- and higher-order relays. Figure 6(a) illustrates key elements of this organization (details reviewed in Sherman, S. M. and Guillery, R. W., 2006). All thalamic nuclei receive a feedback corticothalamic projection from layer 6, and they also have inputs from the thalamic reticular nucleus; not shown for simplicity are inputs to relay cells from interneurons and the parabrachial region (Figure 3). However, while some thalamic nuclei relay subcortical driver inputs to the cortex (Figure 6(a)), others instead relay driver inputs that arise from cortical layer 5, and this appears to be feedforward (Figure 6(b); see Van Horn, S. C. and Sherman, S. M., 2004). We refer to the type of thalamic relay of Figure 6(a) as first order, because this is the first relay of a particular type of subcortical information (e.g., retinal) to the cortex, and that of Figure 6(b) as higher order, because this relays information already in the cortex but from one cortical area to another.

The lateral geniculate nucleus and pulvinar as first- and higher-order relays. Clearly, in this scheme, the lateral geniculate nucleus is a first-order nucleus. As noted above, examples of other first-order nuclei are the ventral posterior nucleus for somesthesis and the ventral (or lemniscal) portion of the medial geniculate nucleus for sounds. The pulvinar is mostly a higher-order nucleus. We say "mostly" here, because a small part of the pulvinar appears to relay driver information from the superior colliculus (Kelly, L. R. *et al.*, 2003), which would make this portion of the pulvinar first order. Examples of other higher-order thalamic nuclei are most of the posterior medial nucleus for somesthesia, most of the medial and dorsal (or nonlemniscal) portion of the medial geniculate nucleus for hearing, and the medial dorsal nucleus, which widely innervates the prefrontal cortex. Again, most here refers to the fact that some of these nuclei may contain first-order circuits: there is a spinothalamic zone of the posterior medial nucleus and an inferior collicular input to the nonlemniscal part of the medial geniculate nucleus. This possible complex organization of higher-order nuclei has to be clarified, and it will not be considered further here, but it does point up a potential shortcoming of classically defined, cytoarchitectonic boundaries for functional thalamic relays.

The key to this division of thalamic relays into first and higher order is the observation that the layer 5 inputs to relay cells have the same properties as do the subcortical drivers (e.g., retinal input to the lateral geniculate nucleus and medial lemniscal input to the ventral posterior nucleus). Support for

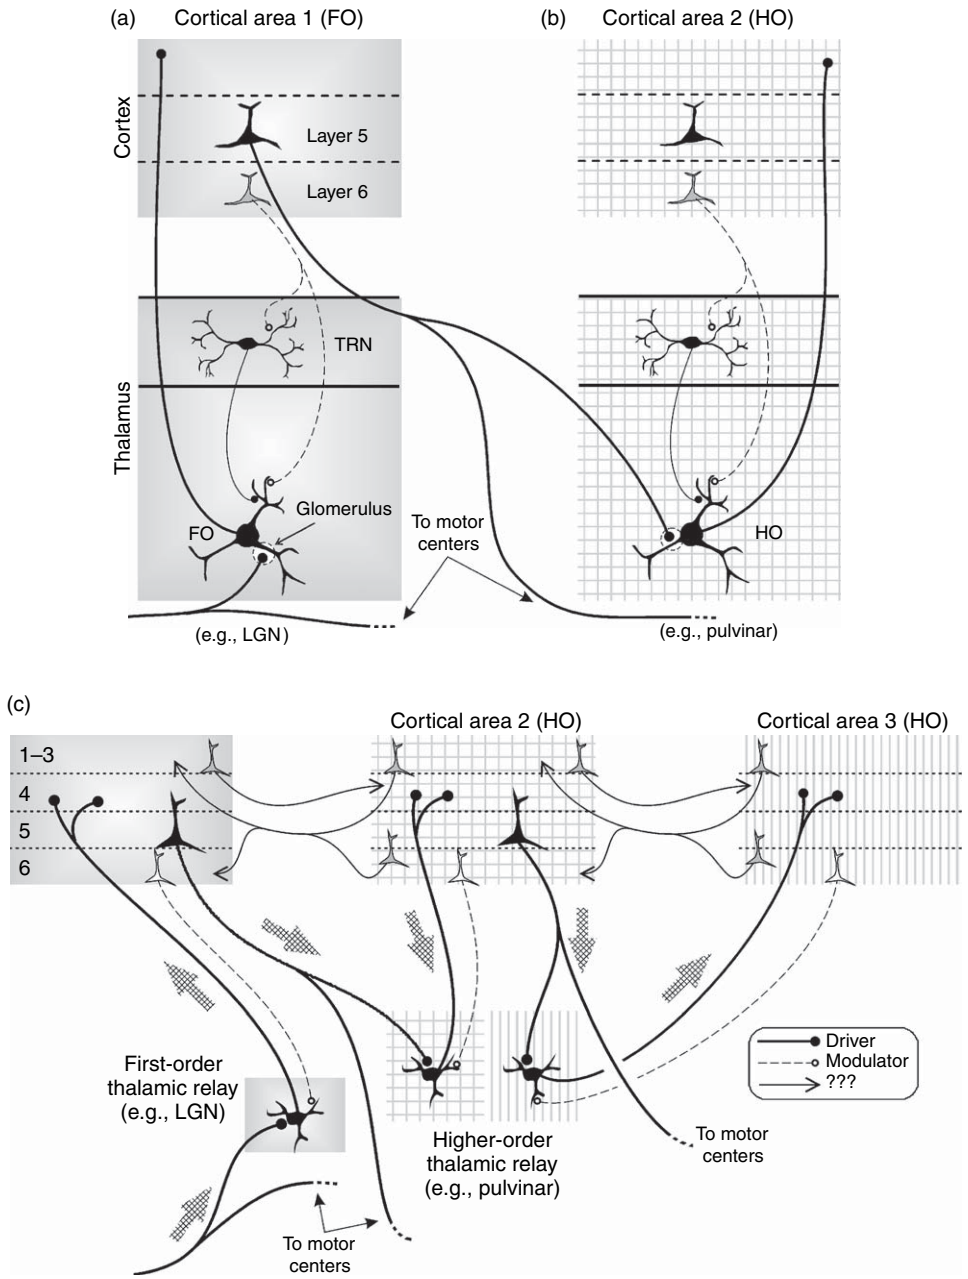

Figure 6 Schematic diagrams showing organizational features of first- and higher-order thalamic nuclei. (a, b) Distinction between first- and higher-order thalamic nuclei. A first-order nucleus (a) represents the first relay of a particular type of subcortical information to a first-order or primary cortical area. A higher-order nucleus (b) relays information from layer 5 of one cortical area to another. This relay can be between first- and higher-order cortical areas as shown or between two higher-order cortical areas. The important difference between them is the driver input, which is subcortical (a) for a first-order thalamic nucleus and from layer 5 of cortex (b) for a higher-order one. Note that all thalamic nuclei receive an input from layer 6 of cortex, which is mostly feedback, but higher-order nuclei in addition receive a layer 5 input from cortex, which is feedforward. (c) Role of higher-order thalamic nuclei in corticocortical communication. This involves a projection from layer 5 of cortex to a higher-order thalamic relay to another cortical area. As indicated, the role of the direct corticocortical projections, driver or modulator or other, is unclear. Note in (a)–(c) that the driver inputs, both subcortical and from layer 5, are typically from branching axons, the significance of which is elaborated in the text. FO, first order; HO, higher order; LGN, lateral geniculate nucleus; TRN, thalamic reticular nucleus. Redrawn from Sherman, S. M. 2005. Thalamic relays and cortical functioning. Prog. Brain Res. 149, 107–126.

this can be found in Table 1: note from the first two columns of Table 1 that the layer 5 input to higher-order relays matches retinogeniculate input on all criteria; in contrast, the second and third columns show that the corticothalamic inputs from layers 5 and 6 differ on all criteria (Reichova, I. and Sherman, S. M., 2004; Sherman, S. M. and Guillery, R. W., 2006; Lee, C. C. and Sherman, S. M., unpublished).

1.28.7.2 Branching of Driver Afferents to Thalamus

Figures 6(a) and 6(b) also shows that the driver inputs to both first- and higher-order relay cells are delivered mostly or wholly via branching axons, with one branch innervating thalamic relay cells and the other innervating extrathalamic targets in the brainstem and spinal cord that are generally motor in nature (Guillery, R. W., 2003; 2005; Sherman, S. M. and Guillery, R. W., 2006). For instance, most or all retinogeniculate axons branch to innervate the pretectum and/or superior colliculus, and, likewise, most or all layer 5 corticothalamic axons branch to innervate motor targets in the pons, midbrain, medulla, and sometimes even spinal cord. However, drivers do not branch to innervate the thalamic reticular nucleus. This is in contrast to most modulator inputs, which do branch to innervate the thalamic reticular nucleus but often have no extrathalamic targets. Limited data are consistent with a similar arrangement for relays of somatosensory and auditory information (reviewed in Guillery, R. W., 2003; 2005; Sherman, S. M. and Guillery, R. W., 2006), and so are not limited to the lateral geniculate nucleus and pulvinar. Guillery R. W. (2003; 2005) has described this feature of driver afferents and suggested what its functional significance might be; this is briefly outlined below.

One interpretation of this pattern of branching to innervate extrathalamic motor targets is that the information actually relayed by thalamus relates to motor commands, starting with first-order relays as perhaps quite crude commands that are constantly upgraded with further cortical processing and effected via higher-order layer 5 cortical outputs. If so, then even first-order sensory processing involves processing of motor commands, a notion that stands conventional views of early visual processing on its head. That is, conventionally, the primary visual cortex (V1) is generally viewed as a purely sensory structure, and this view seems at odds with the idea that V1 is processing motor information. Furthermore, as already noted, V1 (and, indeed all cortical areas so far studied) has a layer 5 projection that branches to innervate pulvinar and extrathalamic motor targets, so that even the corticofugal outputs of V1 have a motor tag according to this perspective. The conventional wisdom that V1 or any other visual, auditory, or somatosensory area is purely sensory is challenged by the observation that all of these areas have a motor output.

1.28.7.3 Role of Higher-Order Thalamic Relays in Corticocortical Processing

Figure 6(c) illustrates the suggested role played by higher-order thalamic relays. After initially reaching the cortex via a first-order relay, such as the lateral geniculate nucleus, information is then passed on to higher-order cortical areas through higher-order thalamic relays. This can involve a number of hierarchical levels of both cortical and thalamic processing. The obvious question raised here is: if the corticothalamocortical pathways involving higher-order thalamic nuclei represent a significant information route, what of the direct corticocortical projections? The answer, simply, is not yet available, but to help clarify the issue here, it is useful to consider three obvious hypotheses, among others.

One possibility is that all direct corticocortical pathways are modulators, in which case all information between cortical areas is relayed via the thalamus. One conclusion that could be drawn here is that all new information that reaches the cortex, whether originating from a subcortical source such as the retina or from another cortical area, benefits from a thalamic relay. That is, for the same reason that retinal information is relayed by the lateral geniculate nucleus and does not project directly to the visual cortex, information from one cortical area to another is relayed through thalamus. Benefits could include gating properties of the thalamus, the burst/tonic transition, etc.

One problem with this hypothesis is that higher-order relays such as the pulvinar may not have enough neurons to relay all of the requisite information needed for cortical processing. Although the pulvinar is the largest thalamic nucleus and dwarfs the lateral geniculate nucleus, Van Essen D. C. (2005) points out that pulvinar neurons may be insufficient in number to relay all information needed for corticocortical communication. A very small percentage of visual cortical neurons are represented by the layer 5 efferents that could provide the afferent link in the corticothalamocortical pathway (Callaway, E. M. and Wiser, A. K., 1996), and these numbers do not

seem to pose a limitation on the role of the pulvinar as a central relay structure between cortical areas. Unfortunately, we as yet have no answer to this general question, because we simply do not know the nature or neural coding of this information that is passed on, and our ignorance here is such that we cannot rule out the possibility that the small number of layer 5 efferent cells is sufficient to this task. It is also possible that the full extent of information processed in a cortical area requires an additional, corticocortical route, the case to which we now turn.

The second hypothesis is that the corticothalamocortical pathways involving higher-order thalamic nuclei serve a modulatory role with all information carried by direct corticocortical projections. For instance, Van Essen D. C. and co-workers (Olshausen, B. A. *et al.*, 1993; Anderson, C. H. *et al.*, 2005; Van Essen, D. C., 2005) have suggested that pulvinar projections to the cortex serve to regulate attentional responses, which, in turn, implies that these projections could act as modulators. However, evidence does exist that the relevant synapses in corticothalamocortical pathways – namely, the layer 5 corticothalamic projections and the higher-order thalamocortical projections – are drivers (Reichova, I. and Sherman, S. M., 2004) (Agmon, A. and Connors, B. W., 1991; Stratford, K. J. *et al.*, 1996; Castro-Alamancos, M. A. and Connors, B. W., 1997; Gil, Z. *et al.*, 1999; Lee, C. C. and Sherman, S. M., unpublished).

The third and final hypothesis is that the higher-order corticothalamocortical and direct corticocortical pathways represent two parallel, largely independent, and complementary routes of information flow. One example of this would be that the very large corticocortical projection handles all of the details of information that must be analyzed about the environment, and the corticothalamocortical projections inform the target cortical area about motor commands initiated by the source area. This is a more limited form of information but is essential, because higher-order cortical areas must maintain a real-time appreciation of how motor commands affect sensory processing. For example, higher-order visual cortical areas need to be able to factor in eye movements that cause the visual world to move on the retina and not view these as movement in the environment. This example of the limited sort of information carried by the corticothalamocortical pathways is consistent with the motor branches of the layer 5 axons described above.

Two further points need to be emphasized here. First, even if both pathways are involved in information flow, there is an important distinction to be made. Whatever information is carried by direct corticocortical connections, this remains in the cortex and is thus different in kind from information carried by the layer 5 outputs to higher-order thalamic nuclei, because as noted above, these layer 5 axons branch to carry the same information to various extrathalamic, subcortical targets. Second, even if some corticocortical projections carry information, the massive potential problem remains to determine which pathways are modulators and which are drivers. This assumes that the driver/modulator distinction makes sense for intracortical pathways, and some recent evidence suggests the plausibility of this. That is, Lee C. C. and Sherman S. M. (unpublished) have shown that, while both first- and higher-order thalamocortical inputs to layer 4 cells in mice have driver synaptic characteristics, intracortical layer 6 inputs to the same layer 4 cells have modulator characteristics. Identifying the subset of drivers among these direct corticocortical pathways, even if the subset proves to be small, along with a full appreciation of the corticothalamocortical pathways, would allow the creation of a more complete and accurate hierarchical scheme for cortical processing.

1.28.7.4 Overview

To help appreciate cortical processing according to the conventional view and how this departs from the alternative view offered here, Figure 7 shows schematically how different these are. In the conventional view, information is relayed by the thalamus to the sensory cortex and passes within the cortex to the sensorimotor and then to the motor cortex before an output is generated to motor centers (Figure 7(a)). This provides no specific role for most of thalamus, which we have defined as higher order, although there are suggestions that some of these thalamic nuclei could play a modulatory role related to attention (Olshausen, B. A. *et al.*, 1993; Anderson, C. H. *et al.*, 2005; Van Essen, D. C., 2005). The alternative view (Figure 7(b)) differs from the beginning, since initial information to be relayed via a first-order thalamic nucleus is a copy of information sent to motor structures. From the primary cortex, information can be relayed to other cortical areas via higher-order thalamic nuclei, and this continues through the various hierarchical stages. Also, these pathways involve layer 5 corticothalamic axons that branch to innervate extrathalamic motor structures. The role of direct corticocortical pathways remains unclear in this view, but it is plausible that there are

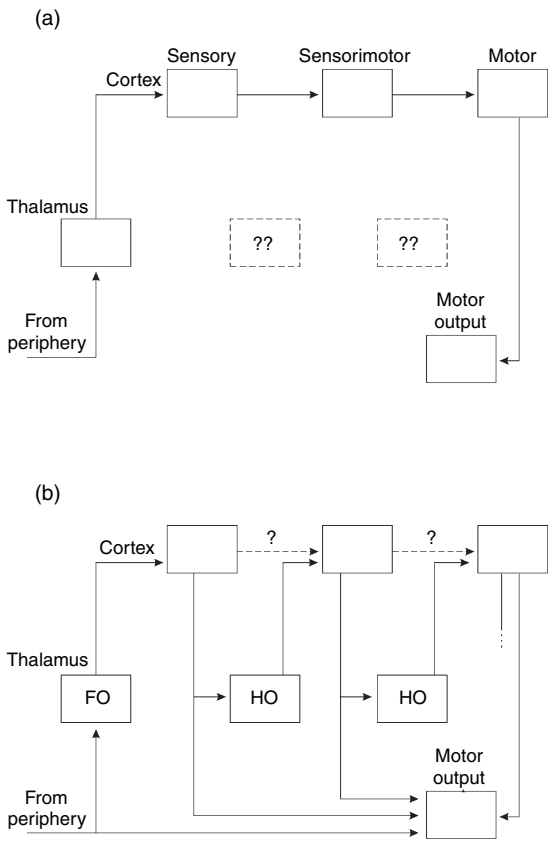

Figure 7 Comparison of conventional view (a) with the alternative view proposed here (b). The role of the direct corticocortical connections in (b) (dashed lines) is questioned (see text for details). FO, first order; HO, higher order. Further details in text. Reproduced from Sherman, S. M. 2005. Thalamic relays and cortical functioning. Prog. Brain Res. 149, 107–126.

two information routes operating independently and in parallel: one is the direct corticocortical route and the other the corticothalamocortical route.

It seems most likely that higher-order thalamic nuclei play an important and hitherto unappreciated role in corticocortical communication. Thus, thalamus is not there just to get information to the cortex in the first place but rather continues to play a role in further cortical processing of that information. What is less clear is the role of direct corticocortical pathways and their relationship to the corticothalamocortical pathways. If the driver/modulator has relevance for these pathways, and that is a major proviso, then it will be essential to identify which of these pathways, if any, are drivers. Only then can we have a clearer understanding of processing among the related cortical areas.

1.28.8 Conclusions

We have progressed from the days when the thalamus was seen as a dull, machine-like relay, providing interesting behaviors only during epilepsy or slow-wave sleep. To a large extent, this misconception grew out of the success of the receptive field approach to the study of sensory systems, particularly vision. Studies of the retina showed that receptive fields become increasingly complicated as one ascends synaptic hierarchies, leading ultimately to the classic center/surround receptive field of ganglion cells projecting to the lateral geniculate nucleus. This process continues across synaptic hierarchies in the cortex, providing cortical receptive fields with exquisite sensitivity to orientation, direction and speed of movement, spatial frequency, stereoscopic depth, etc. This receptive field elaboration in retina and the cortex is ultimately used to encode the sensory environment. The one synapse in the visual system across which no significant receptive field elaboration occurs is the retinogeniculate synapse, since the same basic center/surround organization is seen in retinal afferents and their target geniculate relay cells. This led to the notion that the lateral geniculate nucleus specifically and thalamus more generally represents an uninteresting, simple relay.

We can now turn that view on its head. Indeed, while the rest of the visual and other sensory systems can be ascribed to the same function – that is receptive field elaboration – the thalamus has a completely unique role to play in information processing. Recent appreciation of the complex cell and circuit properties of thalamus makes it clear that it is anything but simple and uninteresting in its functioning. These properties serve to regulate the flow of information to the cortex through mechanisms such as gain control of the retinogeniculate synapse (or equivalent for other nuclei) and the burst/tonic transition, functions that are probably just the tip of the iceberg. Furthermore, we can now see that thalamus is not there just to get information to the cortex but continues to play a significant role in corticocortical communication.

The challenge for students of the visual system is at least twofold. One is to gain a better appreciation of how and under what conditions information is affected before being relayed by the lateral geniculate nucleus or pulvinar to the cortex. The other is to address questions about the pulvinar. One of the great problems here is that we have no complete map of pulvinar that includes a full demarcation of what

regions of pulvinar innervate which regions of the cortex and which are innervated by each cortical area, with a separate mapping of layer 5 and 6 inputs. Given these variables and the presence of more than 30 visual cortical areas with which the pulvinar is involved, it may be that more than a hundred separate pulvinar regions remain to be discovered. This is a daunting task and should be seen as one of the major challenges for future studies of the visual system.

1.29.1 Topographic Maps in Macaque Visual Cortex

One of the defining features of visual cortical areas is a systematic representation of the visual field. Traditionally, microelectrode mapping has been used to determine the relationship between cortical location and receptive field position in the visual field. Cortical maps are described as first-order transformations of the visual field if adjacent points in visual space are mapped to adjacent loci in cortex (e.g., V1). In second-order transformations, the representation of visual space is often split along the representation of the horizontal meridian such that lower fields are generally represented in dorsal cortex and upper fields are represented in ventral cortex (e.g., V2 and V3/VP). Visual field sign has also been used to describe the topography of visual areas. This gradient description of topography is useful in describing the borders between areas that are sampled with low density or that have a somewhat complex internal organization (see Sereno, M. *et al.*, 1994). The topography of any given cortical area can be described by (1) its cortical magnification function (millimeter of cortex/degree of visual angle), (2) the degree of anisotropy of this magnification function (iso-polar vs. iso-eccentricity magnification factor), (3) the proportion of the visual field represented, (4) the topographic order of its representation (first or second order), and (5) its visual field sign.

Functional imaging offers a high-resolution method of topographic mapping in convoluted and buried cortex. In a now famous experiment, 2-deoxyglucose (2-DG) imaging of the topographic organization of macaque striate cortex allowed for precise measurements of cortical magnification factor and anisotropy (Tootell, R. B. H. *et al.*, 1988a; 1988b). In this 2-DG experiment, the monkey monocularly viewed a series of concentric rings and linking rays (Figure 1(a)) while 2-DG was infused. The labeled portions of V1 preferentially accumulated the 2-DG due to their metabolic demand. Figure 1(b) illustrates the representation of this stimulus pattern on an autoradiographic section of the flattened operculum of V1. This experiment provided a direct determination of the cortical magnification factor in foveal and parafoveal striate cortex.

More recently, functional magnetic resonance imaging (fMRI) has been widely applied to determine the topographic organizations and extents of many cortical areas (e.g., Brewer, A. A. *et al.*, 2002; Fize, D. *et al.*, 2003; Tootell, R. B. H. *et al.*, 2004). In general, phase encoding of MR signals, generated in response to sweeping checkerboard sectors or expanding/contracting rings, has become the *de facto* tool for topographic mapping of visual cortex in monkeys and humans (e.g., Sereno, M. I. *et al.*, 1995; DeYoe, E. A. *et al.*, 1996). The remaining portions of Figure 1 illustrate topographic mapping of large portions of macaque visual cortex using this fMRI paradigm. In these experiments, cortical voxels preferentially activated by different stimulus conditions are color coded by stimulus condition and illustrated on unfolded cortical surface maps (Figures 1(c)–1(g)) or on an inflated three-dimensional (3D) cortical surface (Figure 1(h)). In Figure 1(c), three maps are illustrated that indicate the representations of the vertical (blue) and horizontal (yellow) meridian (left panel); foveal (yellow), parafoveal (yellow), and peripheral (blue) visual fields (middle panel); and upper (blue) and lower (yellow) visual fields (right panel). These maps provide a compact representation of a large amount of topographic data and demonstrate that a large portion of occipital and parietal cortex is topographically organized. Figures 1(d)–1(g) illustrate more-detailed views of the representation of polar angle (Figures 1(d) and 1(f)) and eccentricity (Figures 1(e) and 1(g)) at posterior visual cortex (Figures 1(d) and (e)) and occipitotemporal cortex (Figures 1(f)–1(g)). Finally, Figure 1(h) illustrates the projection of these color-coded fMRI activations on a 3D surface reconstruction of the full left hemisphere that was illustrated in Figure 1(g). This method of topographic mapping has proven essential for linking functional activations to specific topographically organized visual areas and for the analysis of less well-understood portions of visual cortex.

1.29.2 Functional Organization of Area V1: Anatomical Modules and Functional Maps

A large number of functional parameters are mapped spatially within primary visual cortex, V1, including ocular dominance, orientation, and hue. Other parameters, such as spatial frequency, temporal frequency, and direction, may also be mapped within V1 of some species (e.g., direction of motion in ferret V1; e.g., Yu, H. *et al.*, 2005), but the evidence of the mapping in macaque monkeys is incomplete. Nevertheless, macaque primary visual cortex has proven to be a model system for understanding how

multiple, functional maps are represented within a single cortical sheet. These investigations have led to new theoretical considerations of the benefits and limitations of such multiparameter mapping within cerebral cortex (e.g., Swindale, N. V., 2000; Malach, R., 1994; Basole, A. *et al.*, 2003; Chklovskii, D. B. and Koulakov, A. A., 2004).

1.29.2.1 Cytochrome Oxidase Modules

Supragranular V1 is organized into cytochrome oxidase (CO)-dense blob and pale interblob regions (Figure 2(a); see Horton, J. C. and Hubel, D. H., 1981). These anatomically defined modules are also distinguished by distinct patterns of inputs from the lateral geniculate nucleus (e.g., Hendry, S. H. and Reid, R. C., 2000), distinct intracortical connections (e.g., Yabuta, N. H. and Callaway, E. M., 1998), distinct projections to extrastriate cortical areas (Sincich, L. C. and Horton, J. C., 2002; Xiao, Y. and Felleman, D. J., 2004), and different functional properties of their constituent neurons (e.g., Landisman, C. E. and Ts'o, D. Y., 2002b). Neurons within the CO blobs tend to lack orientation selectivity and many are color selective, with some displaying dual-opponent receptive fields (e.g., Livingstone, M. S. and Hubel, D. H., 1984), while other cells had color-opponent centers with broadband suppressive surrounds (modified type II; e.g., Ts'o, D. Y. and Gilbert, C. D., 1988). The discovery of CO blobs provided the first clear architectural feature of visual cortex that underlies a functional modular architecture.

1.29.2.2 Ocular Dominance Maps

Projections from the lateral geniculate nucleus are segregated within layer IV (layers IVCα, IVCβ, and IVA for LGN parvocellular and magnocellular inputs) and within layers II–III (for konicellular layer inputs). These inputs form a complex interdigitating 'zebra stripe'-like pattern that can be visualized using anatomical transneuronal transport of tracers following eye injection (e.g., LeVay, S. *et al.*, 1985), histochemical localization of downregulated CO activity following monocular enucleation (e.g., Horton, J. C. and Hocking, D. R., 1998), or by functional imaging of eye dominance domains using alternating monocular stimulation (e.g., Ts'o, D. Y. *et al.*, 1990; Xiao, Y. *et al.*, 1999; 2003). Figure 2b illustrates the V1 ocular dominance pattern in a differential imaging using optical recording of intrinsic cortical signals following alternating monocular stimulation of a multioriented luminance contrast stimulus. V1 is characterized by an alternative banding of ~0.5 mm wide zebra stripes that reflect the segregated projections of monocular inputs from alternating layers of the lateral geniculate nucleus. V1 ocular dominance stripes run roughly perpendicular to the V1–V2 border at which they then end abruptly since V2 is almost completely binocular.

1.29.2.3 Orientation Maps

Neurons located within the CO pale interblob regions tend to be orientation selective and adjacent neurons tend to prefer similar orientations. Furthermore, preferred orientation is mapped systematically across the cortical surface such that large iso-orientation domains that prefer similar orientations are arranged around pinwheel centers (singularities) and fractures in which preferred orientation changes rapidly. This systematic mapping of orientation and its relationship to the color-selective CO blobs is best demonstrated using functional imaging of intrinsic cortical signals (e.g., Bartfeld, E. and Grinvald, A., 1992; Blasdell, G. G., 1992) as illustrated in Figure 2(c). More recently, the visualization of orientation preference has been extended to the cellular level using *in vivo* dual-photon calcium imaging which demonstrated the precision of orientation preference extending up to the pinwheel centers which lack orientation tuning (e.g., Okhi, K. *et al.*, 2005).

1.29.2.4 Hue Maps

Although it has long been recognized that V1 CO blobs tend to contain a high proportion of color-selective cells, there has been little evidence for color differences between blobs (e.g., Landisman, C. E. and Ts'o, D. Y., 2002a; 2002b) or within individual blobs. Recently, however, intrinsic cortical imaging has demonstrated that the peak activation locus for individual hues shifts systematically within individual CO blobs (Figure 2(d); Xiao, Y. *et al.*, 2007). Although there is considerable overlap between the loci within blobs activated by specific hues, these data indicate that the first cortical representation of hue occurs at the level of V1 blobs. Furthermore, these data suggest that the perception of a specific hue is coded by the spatial locus of the peak neuronal population response.

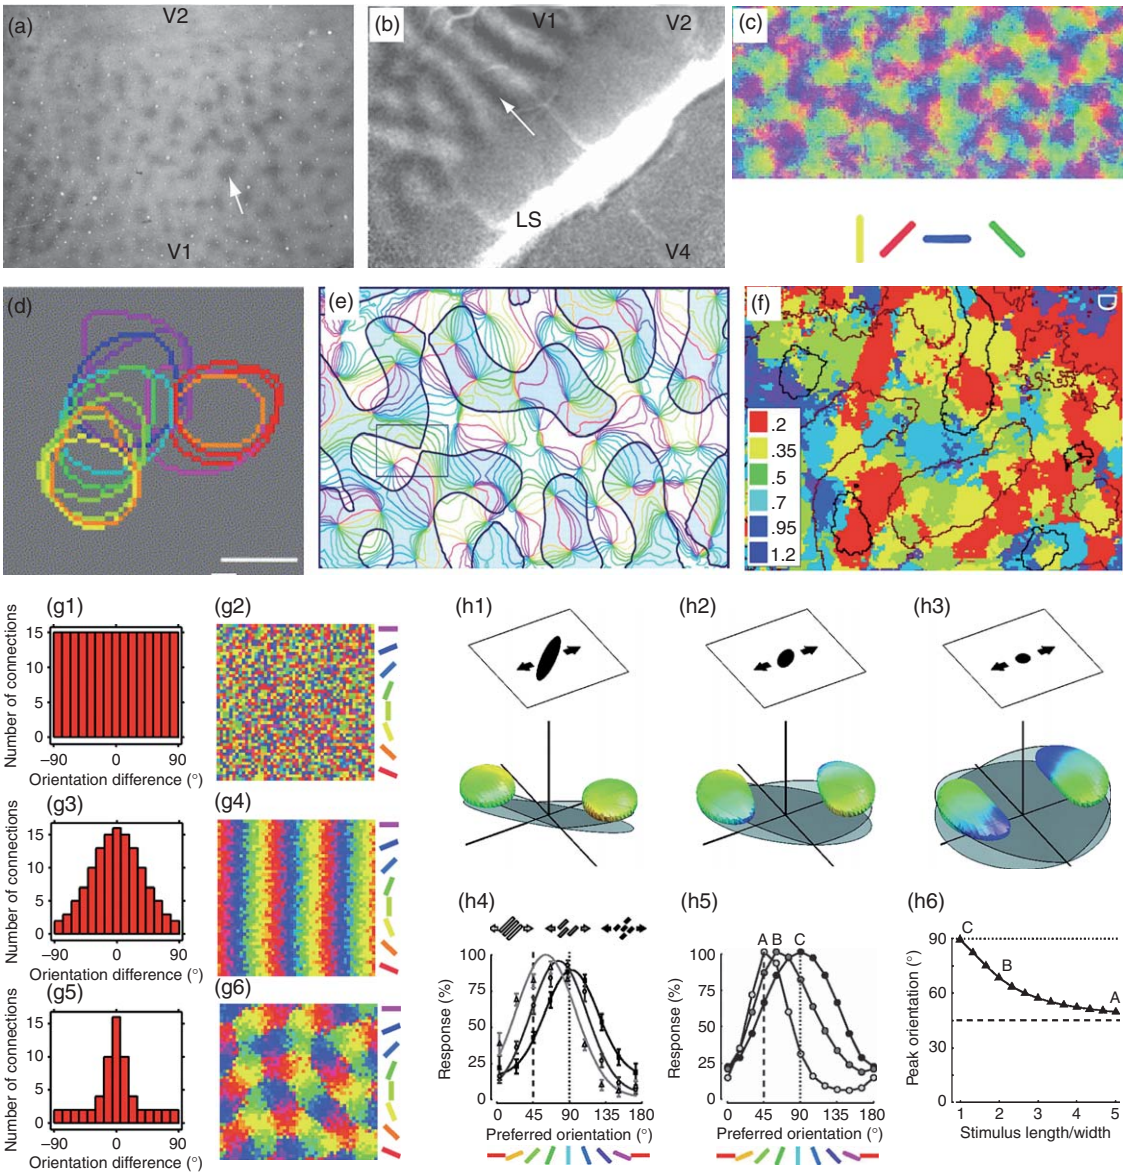

Figure 2 Functional maps and cortical modules in area V1. (a) Cytochrome oxidase blobs (arrow) in flattened macaque V1. (b) Differential intrinsic optical image of left and right eye monocular stimulation reveals the zebra-stripe-like pattern of dominance in macaque V1. V2 and V4 appear as homogeneous gray due to their complete intermixing of left and right eye signals. Neurophysiol. 94, 788–798; (figure 5).

1.29.2.5 Spatial Frequency and Direction Maps

In addition to the systematic mapping of ocular dominance and orientation, V1 of some species also contains systematic maps of spatial frequency and direction of motion (e.g., Weliky, M. *et al.*, 1996; Hübener, M. *et al.*, 1997). Evidence for a columnar and tangential mapping of spatial frequency was first observed in macaque V1 using the 2-DG technique (Tootell, R. B. H. *et al.*, 1981; 1988a; 1988b). Subsequent optical imaging of spatial frequency preference in cat V1 has demonstrated highly ordered maps organized around pinwheels (e.g., Everson, R. M. *et al.*, 1998), continuous spatial frequency maps not organized around pinwheels (e.g., Figure 2(e); Issa, N. P. *et al.*, 2000), or binary spatial frequency maps that simply segregate domains preferring high and low spatial frequencies (e.g., Hübener, M. *et al.*, 1997; Shoham, D. *et al.*, 1997). Furthermore, on methodological grounds, Sirovich L. and Uglesich R. (2004) argued that all cat V1 cortical columns contain both high and low spatial frequency components and thus they are not spatially segregated across the cortical surface. The differences between these conclusions seem to be due to differences in experimental design and analysis largely concerning whether spatial frequency preference is determined across an average of all orientations or only at each pixel's preferred orientation.

1.29.2.6 Interrelationships Among V1 Functional Maps

The relationships among the retinotopic, orientation, ocular dominance, direction, color, and spatial frequency maps in V1 have received considerable experimental and theoretical attention (e.g., Hübener, M. *et al.*, 1997; Mante, V. and Carandini, M., 2005; Yu, H. *et al.*, 2005). In the original 'ice-cube' model of V1, microelectrode recording was used to support the view that each point image in V1 contained a regular progression of orientation slabs (Hubel, D. H. and Wiesel, T. N., 1977). With the advent of intrinsic signal optical imaging, it became possible to visualize the orientation map and to correlate its detailed structure of singularities, fractures, and iso-orientation domains to the coincident ocular dominance pattern (e.g., Hübener, M. *et al.*, 1997). Figure 2(f) supports the conclusion that in the cat, orientation singularities are generally located near the center of ocular dominance stripes and that iso-orientation contours intersect ocular dominance borders at right angles.

The specific relationships among retinotopic, orientation, ocular dominance, and spatial frequency maps were quantitatively examined in ferret V1, which provides the additional constraint of a distinct topographic anisotropy (Yu, H. *et al.*, 2005). When expressed as map feature gradients, previous modeling and experimental data from isotropic visual cortex supported the view that, when two maps interact, the steep gradient of one feature (e.g., ocular dominance) intersects with the low gradient of the other map feature (e.g., iso-orientation). However, in the topologically anisotropic ferret V1, the prediction of two maps intersecting at right angles is unexpected. Yet, the modeling and experimental data from anisotropic ferret V1 demonstrate that for any two maps, the highest gradient regions tend to avoid each other, but they tend not to intersect at right angles to each other (Yu, H. *et al.*, 2005).

In general, CO blobs (and thus hue maps) are centered within ocular dominance stripes (e.g., Bartfeld, E. and Grinvald, A., 1992). However, despite the view that blobs are generally nonoriented, orientation map singularities do not necessarily align with CO blobs (e.g., Landisman, C. E. and Ts'o D. Y., 2002a). Whereas maps of spatial frequency preference have been observed in cat and ferret V1 (e.g., Hübener, M. *et al.*, 1997; Yu, H. *et al.*, 2005), such maps have not been observed in macaque V1, and thus, their potential relationships to CO blobs, orientation maps, and the retinotopic map remain to be determined.

The above discussion of the relationships among the different functional maps suggests that V1 is organized to optimize uniform coverage of neuronal properties at each point image within cortex (e.g., Swindale, N. V., 2000). According to this view, the representations of visual space and feature maps are constrained by the opposing forces of the desirability for adjacent cortical loci to have similar receptive field properties (continuity) and by the desirability for all combinations of stimulus feature maps to be distributed uniformly over visual space (completeness). On theoretical groups, this coverage has been viewed as the consequence of the constraints imposed by dimension reduction.

What constrains the organization of cortical maps? One theory concerns the optimization of 'wiring' length such that neurons with similar receptive field properties (i.e., orientation) are interconnected with the minimal distance as constrained by retinotopic requirements. For example, modeling experiments

by Chklovskii D. B. and Koulakov A. A. (2004) demonstrated that nonbiased orientation connections predict a salt-and-pepper orientation map (Figures 2(g1)–2(g2)), whereas the orientation pinwheel pattern is a consequence of the restricted fan-out of local orientation connections (Figures 2(g5)–2(g6)).

1.29.2.7 Multiple Interdependent Feature Maps or One Spatiotemporal Energy Map?

According to the completeness constraint, a specific combination of stimulus features (as represented in the intersection of multiple, interdependent cortical maps) produces a unique cortical population response, thus supporting the view of a 'place code' for feature representation. The results of multiple optical imaging studies using extended sine wave gratings have supported this view (see above). However, experiments using iso-oriented line segments, varying in length, axis of motion, and speed, have critically challenged this view (Basole, A. *et al.*, 2003). For example, varying the lengths of the bar elements produced a systematic shift in the cortical activation pattern (Figure 2(h4)), a result that was not predicted from a simple orientation-specific activation pattern. Conversely, these experiments demonstrated that a specific cortical activation pattern could be produced by a range of stimuli differing in length, speed, and axis of motion. These results and subsequent modeling experiments (Mante, V. and Carandini, M., 2005) suggest that the cortical population response is better interpreted by a stimulus energy model in which cortical neurons filter the stimulus over restricted regions of 3D frequency space (orientation, spatial, and temporal frequency). According to this model, the reason that the cortical activation pattern varies with changes in iso-orientation bar length (or speed and axis of motion) is that these stimuli differ in their representations in 3D frequency space (Figure 2(h)).

1.29.3 Modular Organization of Area V2

Area V2, like area V1, has a modular architecture defined by the pattern of CO activity. Whereas V1 consists of an interdigitating array of CO blobs anchored to the centers of ocular dominance columns, V2 is characterized by a repeating triplet of CO stripes: CO-dense thick stripes, CO-dense thin stripes, and CO pale interstripes (Figure 3(a)). These stripe triplets, which number approximately 17 per hemisphere (Olavarria, J. F. and Van Essen, D. C., 1997), are oriented perpendicular to the V1 border, extending roughly 6–8 mm in length. Each V2 CO stripe compartment represents an arc of visual space that extends from the vertical to horizontal meridian (Roe, A. W. and Ts'o, D. Y., 1995). Visual space is represented smoothly within each of these CO compartments such that the transition from one stripe to another is characterized by an abrupt jump in receptive field position to re-represent the visual space previously represented (Roe, A. W. and Ts'o, D. Y., 1995). Overall, these V2 stripes can be distinguished by the stimulus parameters that are functionally mapped within their domains.

1.29.3.1 Color, Hue, and Luminance-Change Maps

V2 thin stripes have long been recognized to play an important role in color processing. Early single unit recording experiments identified a high concentration of color-selective cells in thin stripes (e.g., DeYoe, E. A. and Van Essen, D. C., 1985; Shipp, S. and Zeki, S., 1985; 2002), although subsequent studies failed to see large differences between stripe compartments (e.g., Levitt, J. B. *et al.*, 1994) except regarding the clustering of nonoriented, color-selective cells in thin stripes (Gegenfurtner, K. R. *et al.*, 1996). The functional clustering of color selectivity in thin stripes is best revealed in a differential 2-DG experiment that compared responses to isoluminant red-blue and luminance contrast gratings (Tootell, R. B. H. *et al.*, 2004; Figure 3(b)). In optical recording experiments, V2 thin stripes are preferentially activated in differential images in response to isoluminant red/green gratings versus luminance contrast gratings (Figure 3(c)). This result suggests that a preponderance of thin stripe neurons is selective for chromatic contrast, yet close examination of these images demonstrates that thin stripes contain both chromatic-selective (dark) and luminance-selective (bright) domains (Figure 3(d)). These domains are not selective for orientation in that chromatic or luminance gratings of different orientations activate nearly identical thin stripe loci. Within the chromatic-selective domain, individual isoluminance hue stimuli maximally activate restricted foci roughly 350 μm in diameter. Furthermore, the locations of peak activation foci shift systematically across the cortical surface, often in the order of perceptual color circle (Figure 3(e); Xiao, Y. *et al.*, 2003). Achromatic stimuli of varying luminance levels preferentially activate segregated luminance-change domains depending on whether

the stimulus luminance is greater or less than the preceding background. Variations in the preceding background luminance demonstrate that the evoked optical activity represents the direction of luminance change rather than responses to a specific luminance (Wang *et al.*, 2007; Figure 3(f)).

1.29.3.2 Contour Maps

V2 thick and interstripes contain systematic maps of contour orientation. These V2 contour orientation domains are larger than those in V2 and appear to extend across thick and interstripe boundaries without clear functional borders. V2 orientation domains can be visualized in differential images of orthogonal orientation stimulation using optical recording of intrinsic cortical signals (e.g., Figure 3(g)) and a more complete pattern can be visualized using the vector sum representation of preferred orientation following stimulation with four (or more) orientations (e.g., Roe, A. W. and Ts'o, D. Y., 1995; Figure 3(h)). The full pattern of orientation selectivity in V2 is best seen

in a differential 2-DG experiment that demonstrates robust orientation-specific activity in thick and interstripes, but not in thin stripes (Figure 3(i); Vanduffel, W. *et al.*, 2002). It is interesting to note that V2 contour orientation maps appear to represent the orientation of object contours independent of the low-level feature that defines the contour. Specifically, V2 orientation maps appear nearly identical whether they are derived from luminance contrast or chromatic contrast contours. Similarly, illusory contours, defined by abutting lines, texture contrast, or motion contrast, also appear to activate similar V2 contour orientation domains (Dillenburger, B. C. *et al.*, 2006).

1.29.3.3 Disparity and Motion Maps

V2 thick stripes contain a large proportion of neurons selective for binocular disparity. Differential optical imaging for binocular versus monocular domains in macaques demonstrates disparity-selective domains that are largely, but not completely segregated from color selective domains (Figure 3(j); Ts'o, D. Y. *et al.*, 2001). Neurons centered within these obligatory-binocular compartments are selective for binocular disparity, while neurons near the borders with 'color' stripes are tuned for both color and binocular disparity. In general, the preferred orientations of neurons along 1–1.5 mm long penetrations in these obligatory-binocular stripes were highly consistent, but the preferred binocular disparity could shift systematically from near to far (e.g., Figure 7; Ts'o *et al.*, 2001). However, it remains to be determined whether this shift in preferred disparity is due to the electrode penetration crossing adjacent disparity columns or truly represents a systematic representation of disparity within a single 'disparity column'. Since thick stripes also contain orientation maps, it remains to be determined whether orientation and disparity are systematically represented in V2. Since V2 orientation domains are relatively large (e.g. 1–1.5 mm in width), it is reasonable to expect that preferred disparity is systematically represented within a submodular structure within each orientation domain.

1.29.4 Modular Organization of Area V4

Unlike areas V1 and V2, area V4 does not appear to contain a consistent pattern of CO staining, suggestive of an underlying functional modular architecture. However, functional imaging using optical recording and differential 2-DG visualization, segregated connections with V2 thin and interstripe modules, and anecdotal reports of single unit clustering suggest that V4 contains a functional architecture reminiscent of the thin and interstripe architecture of area V2.

1.29.4.1 V4 Functional Imaging

Functional imaging of hue, luminance, and orientation domains in V4 has proven to be considerably more difficult than in V1 or V2, due perhaps to the effects of anesthesia, intrinsic inhibition, or perhaps less segregation of neuronal properties. Nevertheless, optical imaging of intrinsic cortical signals has been successful in demonstrating V4 orientation modules in single differential images (Figure 4(a)) and in composite maps derived from the responses from four different orientations (Figure 4(b); Felleman, D. J. and Van Essen, D. C., 1991; Ghose, G. M. and Ts'o, D. Y., 1997). Often these orientation-specific responses appear segregated from color-specific activations (Figure 4(b)), while in other cases the orientation-selective responses extend across considerable portions of V4. This widespread pattern of orientation selectivity is more consistent with the pattern of differential orientation responses observed using 2-DG imaging (Figure 4(g); Vanduffel, W. *et al.*, 2002).

Differential optical recording of responses to isoluminant color and luminance contrast stimuli reveals punctuate activations in V4 that are larger than those in V1 (Figure 4(d)) and tend to partially overlap with orientation-specific foci (not shown). The variable size and inconsistent spacing and positions of V4 color activations are best observed in differential 2-DG studies (Figures 4(e) and 4(f)). These studies demonstrate that V4 modules preferentially activated by isoluminant color stimulation tend to be few in number and highly variable in size and thus reveal that the majority of ventral (Figure 4(e)) and dorsal (Figure 4(f)) V4 is not preferentially activated by color.

1.29.4.2 V4 Modular Cortical Connections

The segregation of V4 into functional domains dominated by orientation- or color-selective inputs is supported by studies of its inputs from the CO-defined stripes of V2. In early studies, it was observed that relatively large retrograde tracer injections into dorsal V4 could label either V2 thin or interstripes (but usually both; DeYoe, E. A. *et al.*, 1994; Felleman,

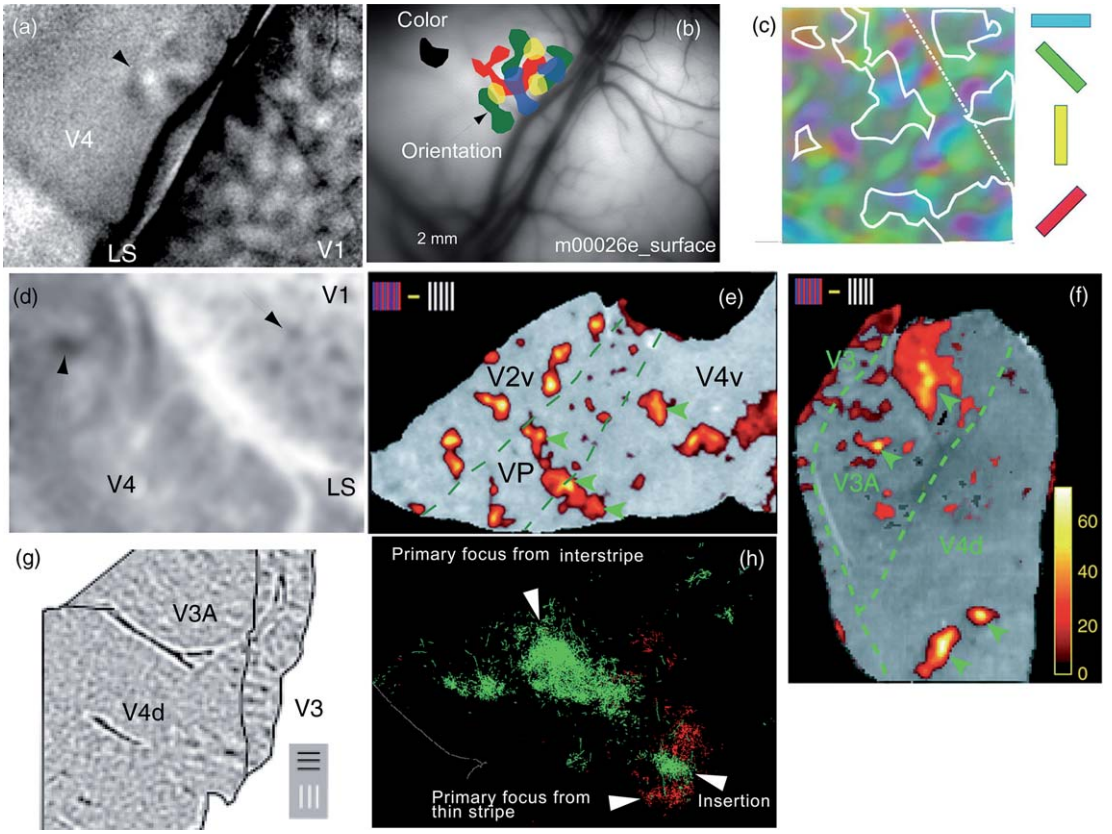

Figure 4 Functional imaging and cortical modules in area V4. (a) Optical recording of orientation-specific (45–135°) activation in area V4. (b) Surface projections of color-preferring (isoluminant red/green – luminance contrast gratings) and orientation map in area V4. (c) Orientation preference map in area V4 (left) and V2 (right). White contours represent S-zones that prefer small luminance stimuli and are suppressed with wide-field stimulation. From Ghose, G. M. Ts'o, D. Y. 1997. Form processing modules in primate area V4. J. Neurophysiol. 77, 2191–2196; (figure 3c). (d) Differential optical imaging of color-preferring foci (isoluminant red/green – luminance contrast gratings) in V4 (left) and V1 blobs (right). (e) Differential 2-deoxyglucose (2-DG) imaging of color-preferring foci in flattened ventral V4. From Tootell, R. B. H., Nelissen, K., Vanduffel, W. and Orban, G. A. 2004. Search for color 'center(s)' in macaque visual cortex. Cereb. Cortex 14, 353–363; (figure 4e). (f) Differential 2-DG imaging of color-preferring foci in flattened dorsal cortex. Area V4d contains few spatially restricted color foci while adjacent area V3A contains larger and more numerous color-preferring domains. From Tootell, R. B. H., Nelissen, K., Vanduffel, W. and Orban, G. A. 2004. Search for color 'center(s)' in macaque visual cortex. Cereb. Cortex 14, 353–363; (figure 5d). (g) Differential 2-DG imaging of orientation-specific activation in flattened dorsal cortex containing V4d, V3A, and V3. From Vanduffel, W., Tootell, R. B. H., Schoups, A. A. and Orban, G. A. 2002. The organization of orientation selectivity throughout macaque visual cortex. Cereb. Cortex 12, 647–662; (figure 12a). (h) Tangential reconstruction of V2 interstripe (green) and thin stripe (red) terminations in V4. From Xiao, Y., Zych, A., Felleman, D. J. 1999. Segregation and convergence of functionally defined V2 thin stripe and interstripe compartment projections to area V4 of macaques. Cereb. Cortex 9, 792–804; (figure 2h).

D. J. *et al.*, 1997). Furthermore, when paired injections separated by ~3 mm were made, cells labeled by the different tracers were sometimes found in the adjacent, segregated thin and interstripes. To visualize directly the size and segregation of this presumed V2 thin stripe and interstripe terminal domains in V4, distinguishable anterograde tracers were injected into adjacent V2 thin and interstripes following their functional characterization using optical imaging (Xiao, Y. *et al.*, 1999). These results indicated that V4 contains large (~12–20 mm^2) domains that receive input from either V2 thin or interstripes. Furthermore, within both the thin stripe and interstripe projection domains, small insertions of projection fields from the other stripe compartment were observed, perhaps providing the anatomical basis for functional interactions between these two cortical streams (Figure 4(h)). This modular

(e) 2-Deoxyglucose (2-DG) image of surround-suppression architecture in owl monkey area MT. Dark regions do not show surround suppression while pale regions are suppressed by the movement of large (>10° stimuli). From Born, R. T. 2000. Center-surround interactions in the middle temporal visual area of the owl monkey. J. Neurophysiol. 84, 2658–2669; (figure 6a). (f) Cortical projections of MT wide-field and local processing modules. Wide-field modules (not suppressed by large stimuli; dark regions) project to ventral area MST and area FSTd while MT local processing modules (suppressed by large field stimuli; pale) project to dorsal portions of area MST. From Berezovskii, V. K. and Born, R. T. 2000. Specificity of projections from wide-field and local motion-processing regions within the middle temporal visual area of the owl monkey. J. Neurosci. 20, 1157–1169; (figure 12). (g) Model of functional architecture of owl monkey area MT. Bands of wide-field and local spatial summation intersect with axis of motion maps. From Born, R. T. 2000. Center-surround interactions in the middle temporal visual area of the owl monkey. J. Neurophysiol. 84, 2658–2669; (figure 15).

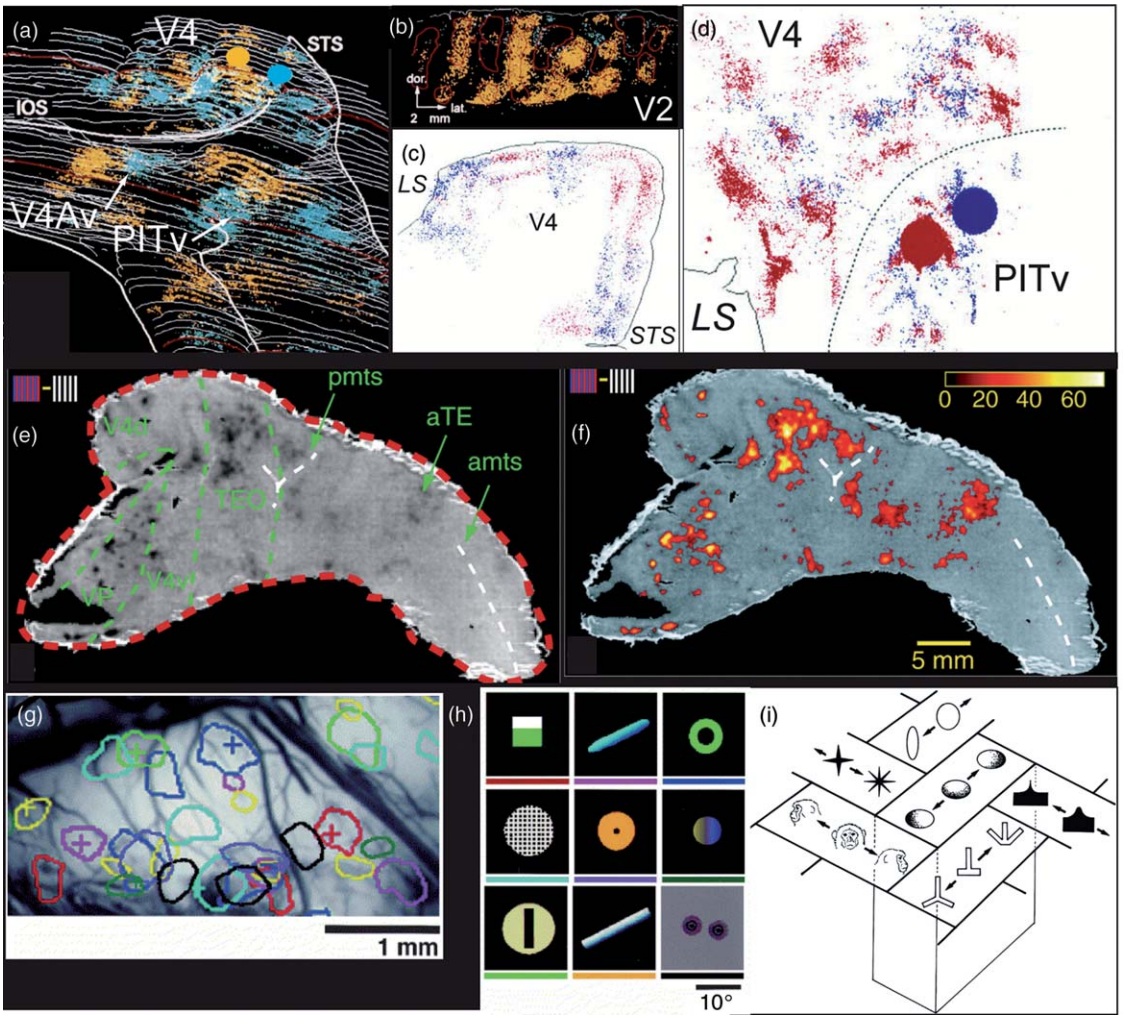
segregation of V2 thin and interstripe inputs, in conjunction with functional imaging evidence for segregated orientation and chromatic domains, suggests that V4 contains at least two functionally distinct modules that appear to maintain largely segregated processing of object surface and contour information.

1.29.5 Modular Organization of Area MT

Area MT is an extrastriate visual area that is characterized by preponderance of directional selectivity and is clearly implicated in perception of the direction of moving objects (e.g., Maunsell, J. H. and Van Essen, D. C., 1983; Newsome, W. T. *et al.*, 1989; Britten, K. H. *et al.*, 1992). In macaque monkeys, MT is buried in the posterior bank of the superior temporal sulcus and thus is not amenable to optical recording studies of columnar or modular organization. However, evidence for a modular organization of orientation preference was derived from a differential 2-DG imaging study that revealed irregular clusters of neurons with preferences for vertical or horizontal orientations (Figure 5(a); Vanduffel, W. *et al.*, 2002).

1.29.5.1 MT Single-Unit Mapping

Many single-unit recording studies have observed stretches of common direction preference attributed to iso-direction columns in macaque MT (e.g., Dubner, R. and Zeki, S. M., 1971). Furthermore, oblique penetrations across MT revealed smooth changes of preferred direction, punctuated by jumps of reversals of preferred direction, suggestive of an orderly map of direction (Albright, T. D. *et al.*, 1984). The resultant model of direction of motion modules in MT was subsequently expanded by DeAngelis G. C. and Newsome W. T. (1999), who demonstrated a columnar organization of binocular disparity tuning within MT such that regions of strong and weak disparity tuning are superimposed upon the direction preference map (Figure 5(b)).



1.29.5.2 MT Functional Maps

Unlike in macaque monkeys, owl monkey MT is located on the exposed cortical surface and thus has been amenable to detailed analyses of orientation and direction maps. Neurons in owl monkey MT tend to be more highly tuned for orientation than their counterparts in macaque monkey MT. Consequently, it was not surprising to find a robust mapping of orientation in owl monkey MT that contained the characteristic pinwheel centers, iso-orientation domains, and orientation fractures (Malonek, D. *et al.*, 1994; Figure 5(c)). In addition, owl monkey MT contains an orderly map of preferred direction, characterized by long stretches of gradual direction change, pinwheels of rapid smooth change, and map fractures indicative of rapid breaks in direction change (Malonek, D. *et al.*, 1994; Figure 5(d)). Surprisingly, the functional map of orientation has larger response amplitude than the functional map of direction.

1.29.5.3 MT Functional Architecture and Projections

In owl monkeys, area MT is also characterized by a modular organization in which neurons with strong antagonistic surrounds are segregated from those that respond well to global motion stimuli (Born, R. T. and Tootell, R. B., 1992; Figure 5(e)). This modular architecture of surround antagonism is also reflected in the pattern of efferent connections such that neurons within the modules with strong surround antagonism project to area MST while neurons with weak surround antagonism project to areas MST and FSTd (Berezovskii, V. K. and Born, R. T., 2000; Figure 5(f)). The available evidence for the modular organization of area MT indicates that a comprehensive model of its functional architecture must include mapping of direction, orientation, and disparity (not shown), center–surround antagonism (local versus global motion processing), and efferent connectivity (Born, R. T. and Bradley, D. C., 2005; Figure 5(g)).

1.29.6 Modular Organization of Inferotemporal Cortex

1.29.6.1 Inferotemporal Areas

Inferotemporal cortex (IT) consists of a number of distinct subdivisions that have been distinguished on

Figure 6 Functional imaging and cortical modules in inferotemporal cortex. (a) Intrinsic and extrinsic connections following V4 retrograde tracer injections that labeled V2 interstripes (yellow injection and cells) or V2 thin stripes (blue injection and cells). Projections from area V4Av, PITv, and more anterior inferotemporal cortex are largely segregated from each other, suggestive of a modular organization that reflects the modular organization of area V2. From DeYoe, E. A., Felleman, D. J., Van Essen, D. C. and McClendon, E. 1994. Multiple processing streams in occipito-temporal visual cortex. Nature 371, 151–154; (figure 1a). (b) Pattern of projections arising from flattened V2 following retrograde tracer injections in panel (a). From DeYoe, E. A., Felleman, D. J., Van Essen, D. C. and McClendon, E. 1994. Multiple processing streams in occipito-temporal visual cortex. Nature 371, 151–154; (figure 1b). (c) Alternating, segregated modular projections across V4 on the prelunate gyrus and posterior bank of the STS following paired retrograde tracer injections into posterior inferotemporal area PITv. From Felleman, D.J., Xiao, Y. and McClendon, E. 1997. Modular organization of occipito-temporal pathways: cortical connections between areas V2, V4, and PITv in macaques. J. Neurosci. 17, 3185–3200; (figure 5a). (d) Segregated, modular projections from V4 to area PITv in a tangential reconstruction of anterior occipital-posterior inferotemporal cortex. From Felleman, D. J., Xiao, Y. and McClendon, E. 1997. Modular organization of occipito-temporal pathways: cortical connections between areas V2, V4, and PITv in macaques. J. Neurosci. 17, 3185–3200; (figure 5f). (e) Differential 2-deoxyglucose (2-DG) imaging of color-preferring modules in unfolded, ventral anterior occipital cortex and inferotemporal gyrus. Dashed green lines indicate the approximate borders between occipital areas V4d, VP, and V4v and inferotemporal areas TEO and anterior TE (aTE). From Tootell, R. B. H., Nelissen, K., Vanduffel, W., and Orban, G.A. 2004. Search for color 'center(s)' in macaque visual cortex. Cereb. Cortex 14, 353–363; (figure 7b). (f) Color-coded 2-DG t-map of color-selective activity from panel (e). Although areas VP, V4d, and V4v contain punctuate color-preferring modules, robust color modules are observed in area TEO and in several patches across middle and anterior TE. From Tootell, R. B. H., Nelissen, K., Vanduffel, W. and Orban, G. A. 2004. Search for color 'center(s)' in macaque visual cortex. Cereb. Cortex 14, 353–363; (figure 7c). (g) Optical imaging of object responses in dorsal anterior TE. Colored contours refer to cortical activations to stimuli (panel (h)) indicated by the same color underbar. Individual stimuli produce multiple cortical activations and different stimuli activate largely segregated portions of TE. From Wang, G., Tanifuji, M. and Tanaka, K. 1998. Functional architecture in monkey inferotemporal cortex revealed by in vivo optical imaging. Neurosci. Res. 32, 33–46; (figure 5). (i) Model of the modular organization of object representation in macaque anterior inferotemporal cortex. Different modules represent different object forms. However, adjacent modules may represent slight variations of a particular object type. From Tanaka, K. 2003. Columns for complex visual object features in the inferotemporal cortex: clustering of cells with similar but slightly different stimulus selectivities. Cereb. Cortex 13, 90–99; (figure 7).

the basis of cytoarchitecture (e.g., Brodmann, K., 1909; von Bonin, G. and Bailey, P., 1947; Lewis, J. W. and Van Essen, D. C., 2000), physiological properties (e.g., Baylis, G. C. *et al.*, 1987), behavioral effects following lesions (e.g., Buffalo *et al.*, 2005; Huxlin *et al.*, 2000), and cortical connections (e.g., Webster, M. J. *et al.*, 1994). Although the exact number of subdivisions or areas that comprise IT remains controversial, there is consensus that posterior subdivisions on the inferotemporal gyrus (ITG), area TEO (or PITv), and area PITd, within the adjacent lateral bank of the superior temporal sulcus, are anatomically and functionally distinct from the more anterior subdivisions. Anterior IT appears to consists of at least four (TEpd, TEpv, TEad, and TEav) and perhaps as many as eight subdivisions on the ITG and adjacent lateral bank of the superior temporal sulcus (e.g., Felleman, D. J. and Van Essen, D. C., 1991; Lewis, J. W. and Van Essen, D. C., 2000; Saleem, K. S. *et al.*, 2000).

Evidence for functional maps or modules within IT comes from several diverse experimental approaches. Posterior IT subdivisions, areas PITv and PITd, appear to be topographically organized based on electrophysiological mapping (e.g., Boussaovd *et al.*, 1991) and cortical connections with topographically organized occipital areas such as V2 and V4 (Van Essen, D. C. *et al.* 1990; 1992; Distler, C. *et al.* 1993). The remainder of IT does not appear to be topographically organized and contains neurons with relatively large receptive fields that almost always include the fovea (Baylis, G. C. *et al.*, 1987; Desimone, R. et al., 1984; Gochin, P. M. 1996).

1.29.6.2 Inferotemporal Anatomical Modules and Connections

Area PITv contains a modular organization that appears to be a continuation of the modular segregation of functional domains observed in areas V2 and V4. Although V4 does not contain an anatomical modular organization corresponding to the CO stripes of V2, it contains large segregated domains that receive input from either V2 thin or interstripes (Xiao, Y. *et al.*, 1999). Furthermore, paired retrograde tracer injections into V4 receive feedforward input from segregated thin and interstripe compartments of V2 and receive feedback projections from segregated modules in PITv (Figures 6(a) and 6(b); DeYoe, E. A. *et al.*, 1994). Similarly, paired retrograde tracer injections into PITv often label highly segregated, yet interdigitating modular domains in V4 (Figure 6(c); DeYoe, E. A. *et al.*, 1994; and Figure 6(d); Felleman, D. J. *et al.*, 1997). These results demonstrate that posterior IT (area PITv in particular) consists of segregated modules that appear to continue the functional segregation of neuronal populations involved in object surface and contour processing. It remains to be determined whether this functional segregation persists at higher levels of inferotemporal object processing or whether these anatomically distinct modules converge at higher levels to form a new functional architecture in anterior IT.

1.29.6.3 Inferotemporal Functional Imaging

The modular organization observed in area PITv on the basis of its segregated afferent connections with area V4 appears to be reflected in regional functional specializations. For example, differential 2-DG imaging, comparing functional activations to isoluminant chromatic versus luminance contrast stimulation, reveals a pattern of 2–3 mm wide hot spots in dorsal (foveal) PITv that are preferentially activated by chromatic stimuli (Tootell, R. B. H. *et al.*, 2004; Figures 6(e) and 6(f)). These foci appear larger and more selective for color than similar foci observed in area V4 and thus may represent the color area, corresponding to the most robust color-preferring domain in macaque visual cortex. Similarly, using fMRI in alert macaques, significant color activations were observed anterior to V4 in a region probably corresponding to area PITd (Conway, B. R. and Tsao, D. Y., 2006).

1.29.6.4 Inferotemporal Functional Modules

Neurons in posterior inferotemporal cortex, including areas PITv and perhaps CITv (TEO and posterior IT) appear selective for particular spatial configurations of relatively low level boundary contours (e.g., Brincat, and Connor, 2004; Pasupathy and Connor, 2001) whereas neurons in more anterior IT are selective for more complex stimuli (e.g., Tsunoda *et al.*, 2001). Furthermore, neurons in anterior IT appear to represent objects despite large variations in size, position, and features (e.g., Lueschow *et al.*, 1994; Sary *et al.*, 1993). Some IT neurons are selective for faces (e.g., Baylis, G. C. *et al.*, 1987; Tsao, D. Y. *et al.*, 2003; Tsao, D. Y. *et al.*, 2006), and although they tended to be encountered more frequently within the superior temporal sulcus, it was not until the application of fMRI mapping of functional specialization within IT was it appreciated that face cells are clustered in two or more IT subdivisions (e.g., Tsao, D. Y.

et al., 2006). Extensive microelectrode recording within IT has led investigators to propose a modular organization for objects within anterior IT in which clusters, roughly 0.5 mm in width, represented specific objects (e.g., Fujita, I. *et al.*, 1992; Tamura, H. *et al.*, 2005). This hypothesis was later confirmed using optical recording of intrinsic cortical signals (e.g., Wang, G. *et al.*, 1998), which demonstrated modular-specific activations (Figure 6(g)) that generalized across related object types (Figure 6(h)). The observation of relatively pure columnar representations of particular objects and the finding that similar objects are represented in adjacent columns led to a hypothesis of a modular organization of object representation within anterior portions of IT (Tanaka, K., 2003; Figure 6(i)). This model of IT implies that the representation of a given object is encoded by the activity of a complex combination of cortical columns or modules (Tsunoda, K. *et al.*, 2001).

1.29.7 Summary and Conclusions

Visual cortex of monkeys is characterized by functional maps and cortical modules that allow for the orderly representations of a large number of sensory attributes within a limited amount of cortical tissue. Most visual areas are topographically organized in that they contain a systematic representation of visual space. In some areas, such as V1, the representation of visual space is very precise and is only disrupted by the differential CO blob and interblob architecture that segregates color/brightness from orientation-specific processing. V1 contains simultaneous functional maps for visual topography, eye dominance, orientation, color/brightness, and perhaps spatial frequency. The topographic organization of area V2 is precise within each CO stripe compartment, but the overall topography is disrupted by functionally specific modules that segregate color/brightness, contour, and disparity processing. Area MT contains at least three functional maps that simultaneously represent visual topography, preferred direction of motion (and/or orientation), and binocular disparity. These functional maps also appear to be distributed across an additional modular system that segregates local from global motion processing, the result of which is distributed along two different efferent cortical streams. Area V4 and inferotemporal area PITv contain topographic maps of visual space, but less is known concerning how other visual attributes are represented. Both areas contain an anatomical modular architecture that appears to continue the anatomical and functional modularity observed within area V2 thin and interstripes. Thus, areas V4 and PITv appear to contain segregated functional modules that independently process object surface and contour information. These functional modules appear to converge at higher levels of IT where a modular organization of 3D object properties emerges. IT contains a modular representation of objects: columns represent specific object types and structurally similar objects appear to be represented within adjacent modules. Overall, these data demonstrate that visual cortical areas generally represent a number of stimulus attributes, simultaneously, and that anatomically and functionally defined modules provide mechanisms for efficient local computation and for efficient segregation of intercortical inputs and outputs.

1.30.1 Introduction

The human visual system contains numerous visual areas that collectively occupy about 27% of the total extent of cerebral cortex (950 cm^2) (Van Essen, D. C., 2003). Typically, visual cortical areas can be identified by four main criteria: retinotopy, global functional properties, histology (cytoarchitecture and myeloarchitecture), and intercortical connectivity (Felleman, D. J. and Van Essen, D. C., 1991; Kaas, J. H., 1997; Tootell, R. B. *et al.*, 2003). Over the past decade, noninvasive neuroimaging methods, especially functional magnetic resonance imaging (fMRI), have greatly clarified the retinotopic organization and functional properties of the human visual system (Tootell, R. B. *et al.*, 1996; 1998b; 2003; Grill-Spector, K. and Malach, R., 2004). Several studies have also explored histological differences between human brain areas in postmortem specimens, but these data have been largely restricted to early visual areas (Horton, J. C. and Hedley-Whyte, E. T., 1984; Horton, J. C. *et al.*, 1990; Clarke, S., 1994a; 1994b; Tootell, R. B. and Taylor, J. B., 1995). More recently, anatomical MRI and diffusion tensor imaging (DTI) have revealed histological and connectional distinctions between areas as well (Conturo, T. E. *et al.*, 1999; Hagmann, P. *et al.*, 2003). Based on these criteria, human visual cortex can be tentatively parceled into more than a dozen distinct areas (Figure 1) (e.g., Tootell, R. B. *et al.*, 2003). In this chapter, we summarize our current understanding of visual cortical organization in humans. Visual areas will be classified and reviewed in four sections: occipital visual areas, ventral stream areas, dorsal stream areas, and frontal areas.

1.30.2 Occipital Visual Areas

The visual cortical hierarchy begins with occipital areas, which are involved in early visual processing. Topographic (retinotopic) mapping (Figure 2) is a

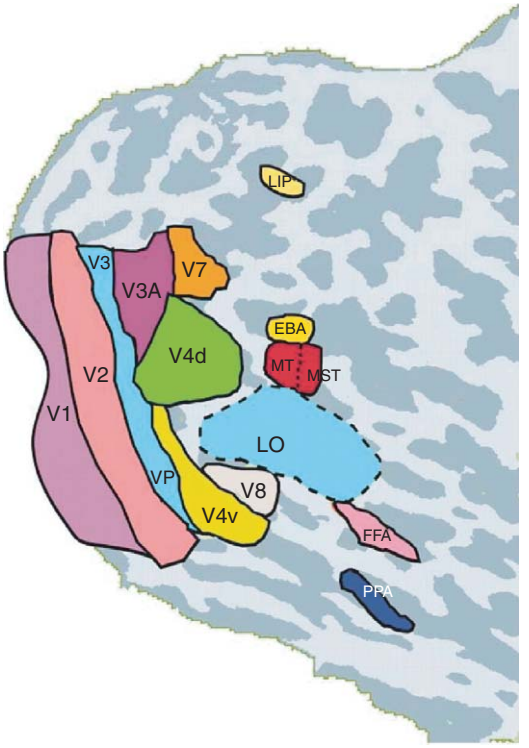

Figure 1 Map of reported areas in human visual cortex. Consensus is highest in lower-tier (generally, leftmost) areas; such areas tend to be evolutionarily more conserved, and the retinotopy is more easily resolved. Adapted from Tootell, R. B., Tsao, D., and Vanduffel, W. 2003. Neuroimaging weighs in: humans meet macaques in "primate" visual cortex. J. Neurosci. 23, 3981–3989.

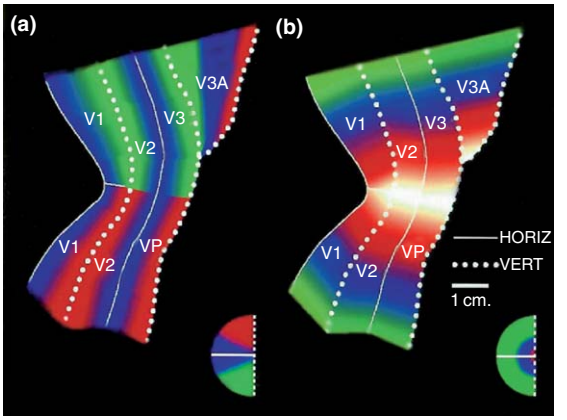

Figure 2 Principles of functional magnetic resonance imaging (fMRI) retinotopic mapping. (a) The polar angle retinotopy and (b) the eccentricity retinotopy. In (a), each of the red, blue, and green pseudocolor ranges represents retinotopically differentiable activation within a 60° subdivision of polar angle in the contralateral visual field (see *logo*, a). In (b), the red, blue, and green ranges correspond to activation within logarithmically equal subdivisions of the eccentricity range from 0.75 through ~15° in the visual field, centered at ~1.5° (red), 3.8° (blue), and 10.3° (green) (see *logo*, b). Adapted from Tootell, R. B., Mendola, J. D., Hadjikhani, N. K., Ledden, P. J., Liu, A. K., Reppas, J. B., Sereno, M. I., and Dale, A. M. 1997. Functional analysis of V3A and related areas in human visual cortex. J. Neurosci. 17, 7060–7078.

ubiquitous property of occipital visual areas in both human (Engel, S. A. *et al.*, 1994; Sereno, M. I. *et al.*, 1995; DeYoe, E. A. *et al.*, 1996; Engel, S. A. *et al.*, 1997a; Hadjikhani, N. K. *et al.*, 1998; Wandell, B. A., 1999; Tootell, R. B. and Hadjikhani, N. K., 2001) and non-human (Gattass, R. *et al.*, 1981; Van Essen, D. C., *et al.*, 1984; Gattass, R. *et al.*, 1988; Tootell, R. B. *et al.*, 1988; Brewer, A. A. *et al.*, 2002; Fize, D. *et al.*, 2003) primates. A visual cortical area is called retinotopic (or said to contain a retinotopic map) if nearby cortical regions receive inputs from nearby retinal regions. Mapping between the retina and the cortex can be best described as a log-polar transformation (Schwartz, E. L., 1977), in which standard axes in the retina are transformed into polar axes in the cortex: eccentricity (distance from fovea) and polar angle (angle from horizontal axis). The logarithmic component of the transformation accounts for the magnification of central representations in the cortex (Schwartz, E. *et al.*, 1985; Duncan, R. O. and Boynton, G. M., 2003).

Mapping the phase (angle) component of the retinotopic map reveals multiple horizontal and vertical meridian representations arranged in approximately parallel bands along the cortical surface. These vertical and horizontal meridian representations alternate and define the borders between mirror-symmetric retinotopic areas. Perpendicular to these bands lie isoeccentricity bands. In humans, the expanded foveal representation of low-level retinotopic areas converges in the occipital pole, in the confluent fovea. Flanking the confluent fovea, there are bands of parafoveal/peripheral representations present both ventrally and dorsally.

1.30.2.1 Primary Visual Cortex

Area V1 (also known as primary visual cortex, striate cortex, or Brodmann's area 17) is the human visual cortical area with the most well-defined anatomical boundaries (Brodmann, K., 1909; Holmes, G. and Lister, W. T., 1916; Von Economo, C. and Koskinas, G. N., 1925; Polyak, S. A., 1933; Stensaas, S. S. *et al.*, 1974). In primates, area V1 plays a critical role in early visual information processing, because most

visual information ultimately reaching the rest of visual cortex is first funneled through V1 (Felleman, D. J. and Van Essen, D. C., 1991). Presumably, this anatomically complicated routing task is partly why striate cortex is so markedly laminated. In fact, primate striate cortex has been anatomically subdivided into eleven identifiable laminar divisions (labeled 1, 2, 3, 4A, 4B, 4C alpha, 4C beta, 5A, 5B, 6A, and 6B) (Lund, J. S., 1988; Hendry, S. H. *et al.*, 1994) rather than the customary six layers described in most cortical areas. Sublamina 4C alpha receives most of the magnocellular input from the lateral geniculate nucleus (LGN) of thalamus, and sublamina 4C beta receives most of the input from the parvocellular LGN (Hubel, D. H. and Wiesel, T. N., 1972). The name striate cortex is derived from the *stria of Gennari*, a distinctive stripe that represents a dense concentration of myelinated fibers in cortical layer 4B. Recently, several groups have reported the in vivo detection of myelination patterns within the human V1 cortex using advanced MRI techniques (Barbier, E. L. *et al.*, 2002; Clare, S. and Bridge, H., 2005). Ocular dominance columns in human V1 have been also demonstrated by using multiple anatomical stains (Haseltine, E. C. *et al.*, 1979; Hitchcock, P. F. and Hickey, T. L., 1980; Horton, J. C. and Hedley-Whyte, E. T., 1984; Horton, J. C. *et al.*, 1990) and blood-oxygen-level dependent (BOLD)-based fMRI (Menon, R. S. *et al.*, 1997; Cheng, K. *et al.*, 2001).

The V1 is the largest known visual cortical area, and perhaps the largest cortical area, at least in macaques, where multiple cortical area boundaries are best known (Felleman, D. J. and Van Essen, D. C., 1991). In addition, one human fMRI study has estimated that neuronal receptive fields are smaller in V1, compared with those in higher-tier visual areas such as V2, V3/VP, V3A, and V4 (Smith, A. T. *et al.*, 2001).

It is well known that V1 normally extends over the depth and lips of the calcarine fissure. However, there is considerable individual variability in the size, location, and shape of V1, and even more variability in the shape of the calcarine fissure (Stensaas, S. S. *et al.*, 1974; Rademacher, J. *et al.*, 1993). Retinotopic lesion defects (Holmes, G. and Lister, W. T., 1916), electrically induced phosphenes (Penfield, W. *et al.*, 1954), and retinotopic maps in positron emission tomography (PET) (Fox, P. T. *et al.*, 1987) and fMRI (Engel, S. A. *et al.*, 1994; Sereno, M. I. *et al.*, 1995; DeYoe, E. A. *et al.*, 1996; Engel, S. A. *et al.*, 1997a; Tootell, R. B. *et al.*, 1998c) studies all confirm that human V1 has a well-defined topographic organization. Generally, the upper bank of the calcarine sulcus responds to the lower half of visual field, and the lower bank of the calcarine responds to the upper half of visual field. The horizontal meridian in the visual field is mapped onto the base of the calcarine sulcus, and the vertical meridian is represented rostrally at the border between V1 and V2. The central visual field activates the posterior tip of the calcarine sulcus, and the peripheral visual field activates anterior parts of the calcarine. Because of the cortical magnification factor (Engel, S. A. *et al.*, 1994; Sereno, M. I. *et al.*, 1995; Engel, S. A. *et al.*, 1997a), a large portion of V1 in the confluent fovea is devoted to the representation of small, central portion of visual field.

The correspondence between a given location in V1 and in the visual field is very precise: even the retinal blind spot is represented as a monocular region in V1 (Tootell, R. B. *et al.*, 1998c; Tong, F. and Engel, S. A., 2001). As one would predict from its location in the retina, the blind spot is located just inferior (superior in the visual field) to the cortical representation of the horizontal meridian, centered at the represented eccentricity near 15°.

The V1 has been generally considered as a feature preprocessing area where the neurons code for basic stimulus attributes, such as line orientation and motion direction. fMR-adaptation paradigms (Tootell, R. B. *et al.*, 1998c; Fang, F. *et al.*, 2005; Larsson, J. *et al.*, 2006; but see Boynton, G. M. and Finney, E. M., 2003) and pattern analysis of fMRI data (Kamitani, Y. and Tong, F., 2005; Haynes, J. D. and Rees, G., 2005) have confirmed that human V1 has strong first-order (luminance) orientation selectivity, as suggested by numerous studies in macaques (Hubel, D. H. and Wiesel, T. N., 1968). Recent fMRI studies also reveal the existence of asymmetric orientation sensitivity (including oblique effect and radial orientation bias) in human V1 cortex (Furmanski, C. S. and Engel, S. A., 2000; Sasaki, Y. *et al.*, 2006). Processing of first-order motion also originates in V1 (Smith, A. T. *et al.*, 1998; Seiffert, A. E. *et al.*, 2003; Nishida, S. *et al.*, 2003).

V1 also shows selectivity for stimulus color (Engel, S. A. *et al.*, 1997b) and spatial frequency (Tootell, R. B. *et al.*, 1998b). The systematic organization of spatial frequency preference in V1 is remarkably similar to that for retinotopic eccentricity (Tootell, R. B. *et al.*, 1998b).

One characteristic functional property of V1 is that its contrast response varies continuously and monotonically over contrasts greater than ~6% (Tootell, R. B. *et al.*, 1995b; Boynton, G. M. *et al.*,

1996). However, the contrast response in higher visual cortical areas (such as V3, MT, and LOC) is quite different, essentially saturated at contrasts higher than ~6% (Tootell, R. B. *et al.*, 1995b; 1998c; Avidan, G. *et al.*, 2002a).

Pathological damages to V1 usually lead to scotomas (e.g., hemianopia) restricted to corresponding regions of the visual field (Holmes, G., 1918). Interestingly, patients with scotomas are often able to make use of visual information presented to their scotomas, despite being unable to consciously perceive it – a phenomenon called blindsight (Stoerig, P. and Cowey, A., 1997).

1.30.2.2 V2/V3/VP

V2 (roughly, Brodmann's area 18) and V3 (even more roughly, Brodmann's area 19) are located adjacent to V1 and are part of extrastriate cortex, sometimes called the peristriate belt. As in V1, V2 and V3 have well-defined topographical (i.e., polar angle and eccentricity) representations of the contralateral visual hemifield (Engel, S. A. *et al.*, 1994; Sereno, M. I. *et al.*, 1995; DeYoe, E. A. *et al.*, 1996; Engel, S. A. *et al.*, 1997a). Each area has a dorsal part (V2d and V3d, above the calcarine fissure representing the lower visual field) and a ventral part (V2v and V3v/VP, below the calcarine representing the upper visual field). In macaques, there is an asymmetry in the size of V2v versus V2d; V2v is slightly wider than V2d (Olavarria, J. F. and Van Essen, D. C., 1997), but such an asymmetry has not been shown in humans.

A long-unresolved controversy in macaques is whether V3d and VP (ventral posterior area) are independent cortical areas (Burkhalter, A. *et al.*, 1986; Felleman, D. J. and Van Essen, D. C., 1987) or two parts of a common area V3 (Gattass, R. *et al.*, 1988; Lyon, D. C. and Kaas, J. H., 2001). Thus far, these two regions are functionally indistinguishable in the human fMRI data, supporting the latter model. In macaques, areas V3 and VP are unusually thin, relative to the width of their neighboring counterparts V2, V4v, and V3A (Felleman, D. J. and Van Essen, D. C., 1991). However, in humans, V3/VP are just as wide as these neighboring retinotopic areas (Tootell, R. B. *et al.*, 1997; Dougherty, R. F. *et al.*, 2003).

The border between V1 and V2 is the representation of vertical meridian, whereas the border between V2 and V3 is the representation of horizontal meridian. Thereby, V2 and V3 (likewise, V1 and V2) have mirror-symmetric visuotopic organizations. It has been suggested that this mirror-symmetric organization might be crucial for optimizing the wiring length of interareal connections (Van Essen, D. C., 1997). V1, V2, and V3 share a common foveal region (foveal confluence) near the occipital pole. Parafoveal and peripheral field stimuli are represented at increasingly anterior positions, in both ventral and dorsal cortex.

Functionally, V2 and V3 have many properties in common with V1. Cells are tuned to simple properties such as orientation, spatial frequency, and color. In macaques, the responses of many V2 neurons are also modulated by more complex properties, such as illusory contours and figure–ground relationships (von der Heydt, R. *et al.*, 1984; Zhou, H. *et al.*, 2000). FMRI suggests that human V2 may be relatively less sensitive to the illusory contours (Mendola, J. D. *et al.*, 1999) – but alternatively, this could be another case in which single units were simply not tested in the most activated areas (as measured by fMRI).

1.30.2.3 V4/V8

In ventral cortex, the border between V3v and V4v is defined by an upper vertical meridian. Currently, there is debate about what constitutes the anterior border of V4 (Figure 3) (Zeki, S. *et al.*, 1991; Hadjikhani, N. K. *et al.*, 1998; Wandell, B. A., 1999; Bartels, A. and Zeki, S., 2000; Wade, A. R. *et al.*, 2002; Tootell, R. B. *et al.*, 2003; Brewer, A. A. *et al.*, 2005). One proposal is that there is a complete hemifield representation, termed human V4 (hV4), adjacent and anterior to V3v, which might be complementary to the dorsal V3A representation (McKeefry, D. J. and Zeki, S., 1997; Kastner, S. *et al.*, 2001; Wade, A. R. *et al.*, 2002; Brewer, A. A. *et al.*, 2005). In contrast, Tootell and colleagues suggest that V4v has a quarter-field representation, and there is a separate area termed V8, consisting of a hemifield representation, which is located anterior to V4v and rotated relative to V4v (Hadjikhani, N. K. *et al.* 1998). In the V8 model, this area has its own representation of the fovea, quite distinct from the foveal representation in adjacent area V4v. All data place the human color-selective region well inferior to the topographic homologue of dorsal V4, which was the originally proposed site of color processing in macaques (e.g., Zeki, S. M., 1973; Zeki, S., 1980).

Clinical studies reveal that color vision loss (achromatopsia) is correlated with damage in the ventral occipito-temporal cortex (Pearlman, A. L. *et al.*, 1979; Damasio, A. *et al.*, 1980; Zeki, S. A.,

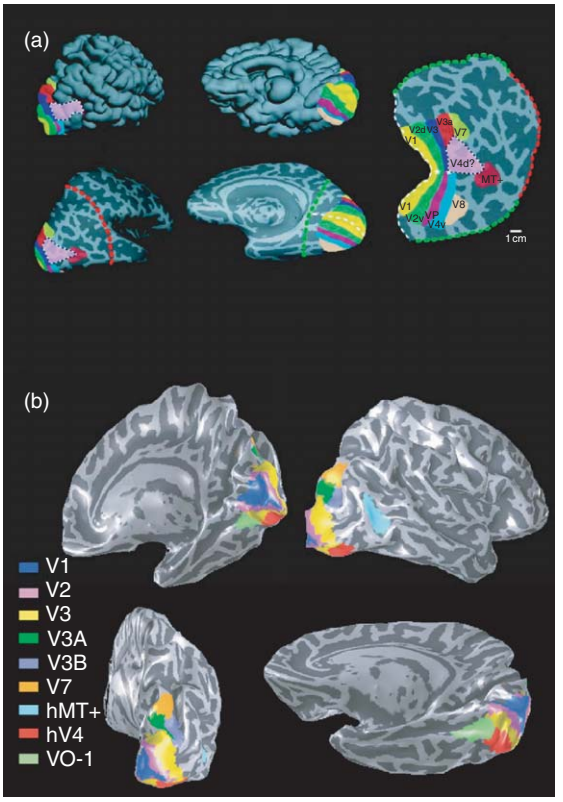

Figure 3 Two proposed models for the retinotopic organization of V4 in humans. The V8 model (a) specifies a quarter-field map, termed V4v, adjacent to the V3v. Anterior to V4v, the model proposes a rotated hemifield representation, termed V8. The hV4 (human V4) model (b) specifies a hemifield map, termed hV4, adjacent to the V3v. Anterior to hV4, the model proposes a cluster of hemifield maps in ventral occipital cortex (VO cluster). The region in the expected location of dorsal V4 (based on macaque V4d) has been assigned a variety of labels such as V4d-topo (a) or V3B (b). Several observations suggest that this region is functionally heterogeneous. (a) Adapted from Tootell, R. B. and Hadjikhani, N. K. 2001. Where is ''dorsal V4'' in human visual cortex? Retinotopic, topographic and functional evidence. Cereb. Cortex 11, 298–311. (b) Adapted from Wandell, B. A., Brewer, A. A., and Dougherty, R. F. 2005. Visual field map clusters in human cortex. Philos. Trans. R. Soc. Lond. B Biol. Sci. 360, 693–707, with permission.

1990). Neuroimaging studies have also shown regions in the vicinity of V4v (but not V4v itself) that respond more strongly to colored patterns than to luminance-defined patterns. These regions are referred to as V8 (Hadjikhani, N. K. *et al.*, 1998; Tootell, R. B. and Hadjikhani, N. K., 2001), the V4 complex (Lueck, C. J. *et al.*, 1989; McKeefry, D. J. and Zeki, S., 1997; Bartels, A. and Zeki, S., 2000), or the ventral occipital (VO) cluster (Wandell, B. A., 1999; Brewer, A. A. *et al.*, 2005). One study has reported that the cortical region V8 is also preferentially activated by color afterimages (Hadjikhani, N. K. *et al.*, 1998). In the V4-complex scheme, this area has been subdivided into two color-selective subdivisions: a posterior structure termed V4 and an anterior one termed V4 alpha (Beauchamp, M. S. *et al.*, 1999; Bartels, A. and Zeki, S., 2000). In the VO-cluster scheme, this cluster has two separate hemifield maps termed VO1 and VO2 (Brewer, A. A. *et al.*, 2005).

1.30.2.4 V5 (Human MT+)

Human MT+ (hMT+) is located at the temporo-parietal occipital junction (Watson, J. D. *et al.*, 1993; Tootell, R. B. *et al.*, 1995b). This region is a central motion-selective locus in the human brain and is a well-accepted homologue of the macaque motion-sensitive area called MT/V5 (Heeger, D. J. *et al.*, 2000; Rees, G. *et al.* 2000; Sereno, M. I. and Tootell, R. B., 2005). hMT+ is selectively activated by moving versus stationary stimuli and exhibits high contrast sensitivity (Tootell, R. B. *et al.*, 1995b). Consistent with psychophysical and electrophysiological findings, fMRI activity in this area decreases when moving color-varying stimuli are equated in luminance (Tootell, R. B. *et al.*, 1995b).

It has been reported that hMT+ contains two distinct subregions, as one might expect from studies of the corresponding region in nonhuman primates. The first subregion (putative hMT) has retinotopic organization but shows little response to peripheral ipsilateral stimulation, indicating smaller receptive fields (Dukelow, S. P. *et al.*, 2001; Huk, A. C. *et al.*, 2002). Conversely, the second subregion within hMT+ (putative human MST or MSTd) has no clear retinotopic organization but responds to peripheral stimuli in both the ipsilateral and contralateral visual hemifields, indicating larger receptive fields (Tootell, R. B. *et al.*, 1998d; Dukelow, S. P. *et al.*, 2001; Huk, A. C. *et al.*, 2002). Retinotopic organization and the relative position of these two subregions in hMT+ are similar to those in the macaque motion areas MT (middle temporal area) and MST (medial superior temporal area) (Gattass, R. and Gross, C. G., 1981; Albright, T. D. and Desimone, R., 1987; Maunsell, J. H. and Van Essen, D. C., 1987). In addition, Dukelow S. P. *et al.* (2001) have reported activity in the anterolateral subsection of the MT+ complex when subjects perform nonvisual pursuit of a self-generated somatosensory target in darkness, suggesting that this region receives extraretinal nonvisual signals,

and thereby corresponds to the human homologue of MSTl (lateral). Some evidence also suggests that there is a functional subregion within the hMT+, which selectively responds to particular radial and circular motion patterns (rather than simple translation) and thus may be involved in calculating optic flow (Morrone, M. C. *et al.*, 2000). Anteroventral to macaque MT/MST, there is another motion-selective area called fundus of the superior temporal sulcus (STS) (FST) (Erickson, R. G. and Dow, B. M., 1989). Currently, no study has reported a human homologue of macaque FST.

Several studies have shown that fMRI activity in hMT+ increases during the perceptual illusion of the motion aftereffect (Tootell, R. B. *et al.*, 1995a; He, S. *et al.*, 1998; Culham, J. C. *et al.*, 1999; Taylor, J. G. *et al.*, 2000; but see Huk, A. C. *et al.*, 2001). Because the motion aftereffect is direction specific, this indicates that hMT+ probably contains direction-selective neural populations, similar to findings in macaques (Maunsell, J. H. and Newsome, W. T. 1987; Britten, K. H. *et al.*, 1992; Salzman, C. D. *et al.*, 1992; Hegger, D. J. *et al.*, 1999). Furthermore, the activation within hMT+ increases linearly with the coherence of motion in random dot patterns (Rees, G. *et al.*, 2000), implying that this area has strong direction selectivity.

hMT+ seems to be mainly involved in global motion processing (Castelo-Branco, M. *et al.*, 2002). For example, hMT+ adapts to patterned motion, in contrast to lower visual areas, which adapt to component motion (Huk, A. C. and Heeger, D. J., 2002). Interestingly, human MT/MST is also activated by static images with implied motion (Kourtzi, Z. and Kanwisher, N., 2000a). Finally, activation of this area is enhanced when subjects attend to or track motion (Buchel, C. *et al.*, 1998; Culham, J. C. *et al.*, 1998).

Thus, converging evidence shows that hMT+ response properties parallel both the response properties of macaque single neurons (Rees, G. *et al.*, 2000) and perception (Muckli, L. *et al.*, 2002). This inference is further supported by clinical studies revealing that akinetopsia (the failure to perceive motion) is associated with lesions in the vicinity of hMT+ (see Zeki, S., 1991, for review).

Adjacent to hMT+, other motion-related cortical sites have been reported. Orban and colleagues described an area termed the kinetic-occipital area (KO) (Dupont, P. *et al.*, 1997; Van Oostende, S. *et al.*, 1997), which is located posterior to hMT+ and specializes in the processing of kinetic boundaries created by discontinuities in motion direction (but see Zeki, S. *et al.*, 2003; Tyler, C. W. *et al.*, 2006). Increasing evidence also suggests a distinct area specialized for perceiving biological motion. This hypothetical area is located within a small region on the posterior STS (STSp) (lateral and anterior to human MT/MST/KO) and is selectively activated during viewing of light-point-defined moving figures (Grossman, E. *et al.*, 2000; Vaina, L. M. *et al.*, 2001; Grossman, E. D. and Blake, R., 2002), but not by the random movement or inverted motion of the same dots that composed the light-point figures. This region is also activated by other types of biological motion such as movies of people walking (Pelphrey, K. A. *et al.*, 2003) or of hand, eye, or mouth movements (Puce, A. and Perrett, D., 2003), or perhaps even implied biological motion (see below).

1.30.2.5 V3A/V3B

After cortical visual areas V3 and V4 were identified and named in macaque monkeys, another region was discovered between them, named V3A (V3 accessory) (Van Essen, D. C. and Zeki, S. M., 1978; Zeki, S. M., 1978a; 1978b). fMRI studies in humans have also revealed a human homologue of V3A (Tootell, R. B. *et al.*, 1997; 1998a; Culham, J. C. *et al.*, 1998; Hasnain, M. K. *et al.*, 1998; Baseler, H. A. *et al.*, 1999; Boynton, G. M. *et al.*, 1999; Mendola, J. D. *et al.*, 1999; Somers, D. C. *et al.*, 1999; Sunaert, S. *et al.*, 1999; Wandell, B. A., 1999). As in macaques, human V3A is regarded as a cortical area that is entirely independent and distinct from its similarly named neighbor, V3, in terms of its retinotopy and functional properties (Tootell, R. B. *et al.*, 1997). Unlike other retinotopic areas in superior occipital cortex (i.e., V1d, V2d, and V3), human V3A has a distinctive, continuous map of the entire contralateral hemifield immediately anterior to area V3 (including a retinotopic representation of both lower and upper visual fields). The inferior vertical meridian is mapped posteriorly (bordering V3), and the superior vertical meridian is mapped at the anterior border of V3A (Tootell, R. B. *et al.*, 1997). The foveal representation is mapped inferiorly, and the periphery is mapped superiorly. In some cases, the V3A foveal representation is displaced from, and located superior to, the confluent foveal representations of V1, V2, V3, and VP (Tootell, R. B. *et al.*, 1997). These properties of human V3A are generally consistent with those described previously in macaque V3A (Tootell, R. B. *et al.*, 2003).

In both macaques and humans, V3A has large receptive fields (Gattass, R. *et al.*, 1988; Tootell, R. B. *et al.*, 1997), which are apparently involved in wide-field visual computations. Such calculations include the processing of binocular disparity (Backus, B. T. *et al.*, 2001; Tsao, D. Y. *et al.*, 2003b; Neri, P. *et al.*, 2004), and illusory contours (Mendola, J. D. *et al.*, 1999). Human V3A is moderately motion-selective, whereas human V3 is less so (Tootell, R. B. *et al.*, 1997; Braddick, O. J. *et al.*, 2001). As in hMT+, contrast sensitivity appears quite high in area V3A (Tootell, R. B. *et al.*, 1997).

Smith A. T. *et al.* (1998) have proposed that V3A (as defined by Tootell, R. B. *et al.*, 1997) may actually consist of two areas, V3A-proper and V3B. In this scheme, both V3A and V3B are located anterior to V3, but V3A borders the peripheral V3 representation, whereas V3B borders the foveal V3 representation. There is no correlate of proposed human area V3B in macaque cortex. Some studies have described a full contralateral hemifield representation in V3B (Press, W. A *et al.*, 2001; Wandell, B. A. *et al.*, 2005; Silver, M. A. *et al.*, 2005), while other groups have reported only a lower contralateral visual quadrant representation in this area (Smith, A. T. *et al.*, 1998; Dumoulin, S. O. *et al.*, 2003). Reportedly, V3B shares a parafoveal representation with V3A. It has motion and disparity specificity like V3A (Smith, A. T. *et al.*, 1998; Greenlee, M. W., 2000) and largely overlaps with the KO area (Zeki, S. *et al.*, 2003).

Tootell R. B. and Hadjikhani N. K. (2001) have discussed a topographic (rather than functional) homologue of macaque dorsal V4 (the V4d topologue), based on neighborhood relations among visual areas (i.e., anterior to V3A, posterior to hMT+, and superior to ventral V4) (Figure 3). V4d-topo incorporates both V3B and KO and hence responds selectively to kinetic motion boundaries. Unlike some previous reports in macaque V4d (Zeki, S. M., 1973; Zeki, S., 1980), human V4d-topo is not significantly color-selective (Tootell, R. B. and Hadjikhani, N. K., 2001).

1.30.2.6 V7

Anterior to V3A lies another representation of polar angle that includes both upper and lower visual fields and is mirror-symmetric to that in V3A. This area has been called V7 (Tootell, R. B. *et al.*, 1998a; 1998b; Tootell, R. B. and Hadjikhani, N. K., 2000; Press, W. A. *et al.*, 2001; Wandell, B. A. *et al.*, 2005; Tyler, C. W. *et al.*, 2005). V7 has a distinct foveal representation (Press, W. A. *et al.*, 2001), and it exhibits robust activity during spatial attention (Tootell, R. B. *et al.*, 1998a; Culham, J. C. *et al.*, 1998). This area may be homologous to the macaque dorsal prelunate (DP) area (Andersen, R. A. *et al.*, 1990; Tootell, R. B. *et al.*, 1998a).

Recently, more topographically organized areas have been reported adjacent and anterior to V7. These areas, labeled IPS1 and IPS2 (IPS: intraparietal sulcus), completely represent the contralateral hemifield and are separated from each other and from V7 by reversals in visual field orientation (Silver, M. A. *et al.*, 2005; Schluppeck, D. *et al.*, 2005). IPS1 and IPS2 are mainly activated during covert shifts of attention or saccadic eye movements (Silver, M. A. *et al.*, 2005; Schluppeck, D. *et al.*, 2005).

1.30.3 Ventral Stream Areas

Cortex anterior to V4 is generally considered part of the ventral (or 'what') processing stream (Ungerleider, L. G. and Mishkin, M., 1982; Mishkin, M. *et al.*, 1983). In macaque, this cortical region includes a cluster of inferotemporal areas that are implicated mainly in pattern recognition and form analysis (Tanaka, K., 1997; Desimone, R. and Ungerleider, L. G., 1989). Similarly, a complex of several subdivisions within human occipito-temporal cortex shows functional specialization in object representation and recognition (Figure 4), so that damage to these regions results in severe visual recognition deficit or agnosia (Farah, M., 1990). Nonetheless, the exact nature of representation in object-related areas is not yet understood. Functional imaging results in humans indicate that object recognition is mediated by both distributed and localized representations. For example, objects such as chairs can be distinguished based on the distributed and overlapping brain activity they elicit, even though no one claims a chair area in cortex (Haxby, J. V. *et al.*, 2001; Spiridon, M. and Kanwisher, N., 2002). However, there are reports of specialized regions in human cortex dedicated to the processing of particular categories such as faces (Kanwisher, N. *et al.*, 1997), places (Epstein, R. and Kanwisher, N., 1998), and body parts (Downing, P. *et al.*, 2001). Malach and colleagues have recently proposed that topographical organization of these specialized regions follows principles of eccentricity mapping (Levy, I. *et al.*, 2001; Malach, R. *et al.*, 2002; Hasson, U. *et al.*, 2002; 2003b; Levy, I. *et al.*, 2004). According to this model, different object categories have specific eccentricity biases (e.g., faces, letters,

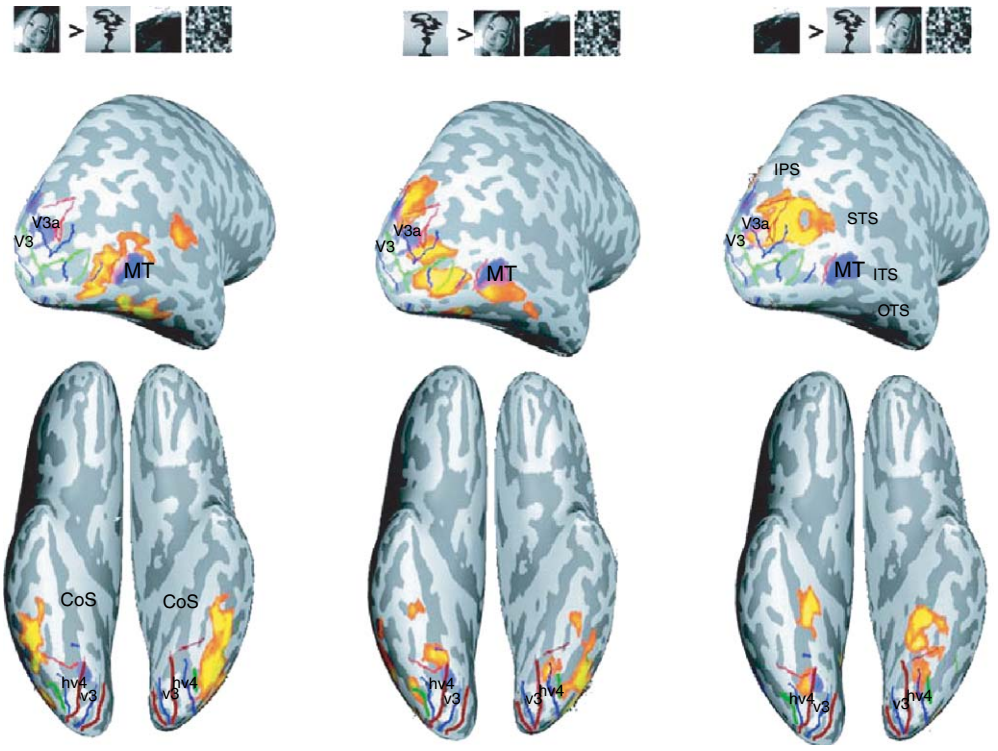

Figure 4 Face-, object-, and place-selective regions in the human brain displayed on an inflated cortical surface. Icons indicate the comparison done in the statistical tests. *Left*: Areas responding more strongly to faces than objects, places, or textures. *Center*: Areas responding more strongly to objects than faces, places, or textures. *Right*: Areas responding more strongly to places (scenes) than faces, objects, or textures. Yellow and orange indicate statistical significance. Colored lines indicate borders of retinotopic visual areas. Blue indicates area hMT+ that responds more strongly to moving versus stationary low-contrast gratings. Adapted from Grill-Spector, K. and Malach, R. 2004. The human visual cortex. Annu. Rev. Neurosci. 27, 649–677, with permission.

and words appear to be associated with central visual field bias, whereas buildings are associated with a peripheral one) (Figure 5). Another putative organizational rule for representation in high-order object areas is that different object categories are topographically represented based on shape-related differences (Fujita, I. *et al.*, 1992; Tanaka, K., 2003). Currently, no systematic investigation has addressed this possibility in human cerebral cortex.

1.30.3.1 Lateral Occipital Complex

Lateral occipital complex (LOC) is a complex of multiple areas in lateral occipital cortex that responds more strongly to a variety of object shapes, as compared with textures, noise patterns, scrambled objects, or scrambled Fourier phase information (which maintains the spatial frequency spectrum) (Malach, R. *et al.*, 1995; Grill-Spector, K. *et al.*, 1998b; 2001). These regions lie anterior and lateral to early retinotopic cortex. Based on fMRI data, the LOC can be divided into at least two putative subdivisions: a dorsal region (LO: lateral occipital) and a more ventral region (LOa: lateral occipital anterior) or pFs (posterior fusiform), along the posterior fusiform gyrus (Grill-Spector, K. *et al.*, 2001). fMRI results in LOC are generally consistent with earlier human PET studies, which had revealed selective activation of ventral and temporal regions associated with the recognition of objects (Haxby, J. V. *et al.*, 1991; Sergent, J. *et al.*, 1992; Kanwisher, N. *et al.*, 1996). This lateral occipital region can be strongly driven by ipsilateral as well as contralateral stimuli (Tootell, R. B. *et al.*, 1998d), and it may have a crude retinotopy (Larsson, J. *et al.*, 2006). The response in LOC is equivalent for familiar and unfamiliar shapes, so the response cannot be obviously accounted for in terms of matching to stored visual representations, or semantic/verbal coding of the stimuli (Malach, R. *et al.*, 1995; Kanwisher, N. *et al.*, 1996; Kanwisher, N., 2003).

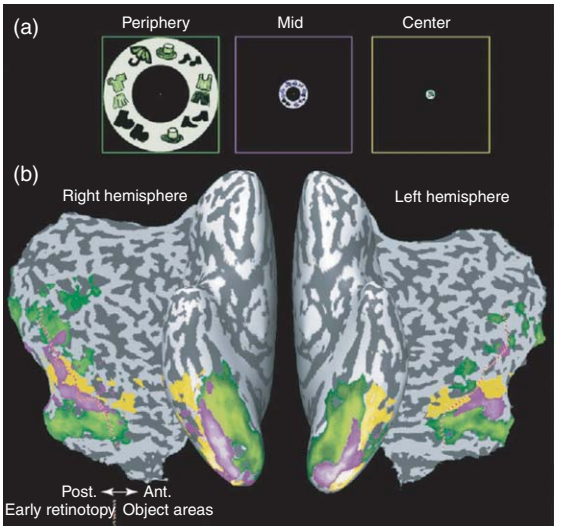

Figure 5 Eccentricity organization of human visual areas. The representations of center (yellow), mid (purple), and peripheral (green) visual field stimuli (a) are shown on a ventral view of the inflated hemispheres and on flattened cortical format (b). The eccentricity mapping is present even in the occipito-temporal cortex. Adapted from Malach, R., Levy, I., and Hasson, U. 2002. The topography of high-order human object areas. Trends Cogn. Sci. 6, 176–184, with permission.

Many studies have shown that the activation in object-selective cortex shows perceptual invariance. Object-selective regions in the ventral stream are activated when subjects view objects defined by luminance (Grill-Spector, K. *et al.*, 1998a), texture (Grill-Spector, K. *et al.*, 1998a; Kastner, S. *et al.*, 2000), motion (Grill-Spector, K. *et al.*, 1998a; Kriegeskorte, N. *et al.*, 2003), or depth cues (Kourtzi, Z. and Kanwisher, N., 2000b; 2001; Gilaie-Dotan, S. *et al.*, 2002), but not when subjects view textures, stationary dot patterns, coherently moving dots, or gratings defined by either motion or stereo. Other studies have shown that activation is independent of object format (photographs or line drawings) (Ishai, A. *et al.*, 2000) and that these regions are also activated when subjects perceive simple shapes created via illusory contours (Mendola, J. D. *et al.*, 1999; Stanley, D. A. and Rubin, N., 2003). Object-selective regions in the ventral stream represent shapes rather than contours or local features (Hasson, U. *et al.*, 2001; Kourtzi, Z. and Kanwisher, N., 2001; Andrews, T. J. *et al.*, 2002; Lerner, Y. *et al.*, 2002) and are more sensitive to the presentation of three-dimensional (3D) volumes relative to 2D shapes (Moore, C. and Engel, S. A., 2001; Kourtzi, Z. *et al.*, 2003a; Welchman, A. E. *et al.*, 2005). However, the unified perception of a global shape (or good Gestalt) may involve both LOC and lower visual areas (V1 and V2) (Murray, S. O. *et al.*, 2002; Altmann, C. F. *et al.*, 2003; Kourtzi, Z. *et al.*, 2003b). Interestingly, some regions within LO even show cross-modality convergence, with stronger activation to objects than textures, for both visually and haptically sensed objects (Amedi, A. *et al.*, 2001; James, T. W. *et al.*, 2002b).

fMR-adaptation paradigms (Grill-Spector, K. and Malach, R., 2001; Avidan, G. *et al.*, 2002b) have revealed more subtle aspects of LOC areas in invariant shape representations. Regions in the occipito-temporal sulcus (OTS) and fusiform gyrus (but not LO) show size and position invariance (Grill-Spector, K. *et al.*, 1999; 2001). In addition, two recent studies show some degree of viewpoint invariance for the representation of objects in ventral occipito-temporal (VOT) when using small rotation angles (James, T. W. *et al.*, 2002a; Vuilleumier, P. *et al.*, 2002; but see Grill-Spector, K. *et al.*, 1999).

Several studies have demonstrated a correlation between object perception and brain activation in lateral and ventral object areas such as LO (Grill-Spector, K. *et al.*, 2000; James, T. W. *et al.*, 2000; Bar, M. *et al.*, 2001; Avidan, G. *et al.*, 2002a; Kleinschmidt, A. *et al.*, 2002; Grill-Spector, K., 2003). In contrast, activity in lower-tier visual areas is not correlated with subjects' percepts in tasks requiring object recognition.

1.30.3.2 Fusiform Face Area

Neuroimaging studies have shown a specific region within the fusiform gyrus that is significantly more active when viewing faces (Sergent, J. and Signoret, J. L., 1992; Haxby, J. V. *et al.*, 1996) compared to other nonface stimuli such as objects (Kanwisher, N. *et al.*, 1997), letter strings (Puce, A. *et al.*, 1996), or houses (Tong, F. *et al.*, 2000). This area has been termed the fusiform face area (FFA) (Kanwisher, N. *et al.*, 1997). Human FFA appears to be topographically homologous to the macaque face patches located in the middle of the STS (Tsao, D. Y. *et al.*, 2003a; 2006). The FFA shows a higher response to upright than inverted faces (Yovel, G. and Kanwisher, N., 2005; but see Epstein, R. A. *et al.*, 2006), suggesting that upright faces are processed holistically in the FFA (see Tanaka, J. W. and Farah, M., 2003, for review). Holistic/configural aspects of face processing may be observed preferentially in the right FFA (Rossion, B. *et al.*, 2000; but see Yovel, G. and Kanwisher, N., 2004). Recently, fMR-adaptation paradigms have elegantly

revealed that the FFA contains subpopulations of neurons, which are selectively tuned to face identity (Rotshtein, P. *et al.*, 2005; Loffler, G. *et al.*, 2005).

FFA activation correlates well with successful face processing but not with successful object processing (Grill-Spector, K. *et al.*, 2004). Other experiments have also used bistable phenomena such as binocular rivalry (Tong, F. *et al.*, 1998), and the Rubin face-vase illusion (Hasson, U. *et al.*, 2001; Andrews, T. J. *et al.*, 2002) to show the correlation of FFA activation with different perceptual states.

Currently, there is debate whether the function of the FFA is truly specific to faces, or whether it instead involves a domain-general operation that could in principle be applied to other stimulus categories. Gauthier and colleagues have argued that the right FFA is an expertise center, responding better to any overtrained visual stimuli, including (but not limited to) faces (Tarr, M. J. and Gauthier, I., 2000). For instance, the FFA is reportedly activated by cars in car experts and by birds in bird experts (Gauthier, I. *et al.*, 2000a). The FFA is also more active when participants become expert at distinguishing computer-generated nonsense shapes known as greebles (Gauthier, I. *et al.*, 1999). These evidence led Tarr M. J. and Gautier I. (2000) to reinterpret the name FFA as the flexible fusiform area. Additional evidence that has challenged the role of FFA in face processing is apparently normal face-related fMRI activation in the FFA in congenital prosopagnosic individuals who are markedly impaired at face processing (Hasson, U. *et al.*, 2003a; Avidan, G. *et al.*, 2005; Behrmann, M. and Avidan, G., 2005).

Early studies of face-selective activation in the cortex have reported that, in addition to the FFA, other cortical areas are selectively active for faces, specifically in the STS and in the inferior and mid-occipital gyri (e.g., Kanwisher, N. *et al.*, 1997; Halgren, E. *et al.*, 1999; Haxby, J. V. *et al.*, 1999; Vaina, L. M. *et al.*, 2001), although in some studies these areas appeared to be less systematically activated (e.g., Kanwisher, N. *et al.*, 1997) or showed a weaker face-selective response (Gauthier, I. *et al.*, 2000b) than did the FFA. Gauthier I. *et al.* (2000b) termed the face-selective inferior occipital area that falls within the larger LOC region, the occipital face area (OFA).

1.30.3.3 Parahippocampal Place Area

The parahippocampal gyrus is a cortical region in the medial temporal lobe that surrounds the hippocampus and plays an important role in both spatial memory (Squire, L. R. and Zola-Morgan, S., 1991) and navigation (Aguirre, G. K. *et al.*, 1996; Maguire, E. A. *et al.*, 1996). The parahippocampal place area (PPA) is a subregion in posterior parahippocampal and anterior lingual cortex that responds preferentially to indoor/outdoor scenes and also to houses/buildings, but not to faces or objects (Epstein, R. and Kanwisher, N., 1998; Aguirre, G. K. *et al.*, 1998). It has been recently demonstrated that the PPA represents scenes in a viewpoint-specific manner (Epstein, R. *et al.*, 2003) and processes the spatial structure of the currently visible environment (Epstein, R. *et al.*, 1999). In addition, activity in the PPA correlates with the scene/house percept (Tong, F. *et al.*, 1998; but see Marois, R. *et al.*, 2004). The evidence for the PPA is supported by neuropsychological patients with topographic disorientation associated with damage in parahippocampal cortex (Habib, M. and Sirigu, A., 1987; Bohbot, V. D. *et al.*, 1998; Aguirre, G. K. and D'Esposito, M., 1999; Epstein, R. *et al.*, 2001).

Recently, Bar and colleagues have shown that the parahippocampal cortex mediates the representation and processing of familiar contextual associations in general, rather than places *per se* (Bar, M. and Aminoff, E., 2003; Bar, M., 2004), and therefore, this region is activated when people recognize highly contextual objects (e.g., a traffic light, houses).

1.30.3.4 Extrastriate Body Area

Downing P. *et al.* (2001) have described a distinct cortical region in humans that responds selectively to images of nonface body parts. This region is located in the lateral occipitotemporal cortex, adjacent to motion-selective MT/MST area, in or near region(s) reportedly activated by the perception of biological motion (Grossman, E. *et al.*, 2000). Peelen M. V. and Downing P. E. (2005) have also reported a fusiform region, so-called the fusiform body area (FBA), which is adjacent to and partially overlaps with the FFA and responds more strongly to headless bodies than to objects (see also Schwarzlose, R. F. *et al.*, 2005).

1.30.4 Dorsal Stream Areas

The human parietal lobes (excluding somatosensory regions) traditionally fall into the category of association cortex because of their complex and multimodal responses (see Zeki, S. M., 1993, for review). Regions of parietal cortex form a major component of the dorsal stream, which is involved in spatial

localization (the 'where' system) (Ungerleider, L. G. and Mishkin, M., 1982) and the control of action (the 'how' system) (Goodale, M. A. and Milner, A. D., 1992). Neuropsychological studies show that patients with parietal damage have attentional disorders (such as hemispatial neglect and simultanagnosia), spatial localization disorders, and sensorimotor coordination problems (Feinberg, T. E. and Farah, M. J., 1997). Single-neuron recordings in macaques also demonstrate numerous regions in parietal cortex that perform highly specialized spatial and sensorimotor functions (Andersen, R. A., 1989; Colby, C. L. and Goldberg, M. E., 1999). Recent neuroimaging studies have identified putative human homologues of macaque parietal regions (particularly regions in the IPS) (Figure 6) (Culham, J. C. and Kanwisher, N. G., 2001; Orban, G. A. *et al.*, 2004; 2006).

1.30.4.1 Caudal Intraparietal Sulcus

Monkey caudal intraparietal sulcus (cIPS) contains neurons selective for binocular disparity and 3D surface orientation and may provide information for the visual guidance of hand action (Sakata, H. *et al.*, 1997; 1998; 1999). Human neuroimaging has identified a region in the caudal end of the IPS that is activated during stereoscopic processing (Tsao, D. Y. *et al.*, 2003b), during object matching and grasping (Faillenot, I. *et al.*, 1997), as well as during discriminations of object size and surface orientation (Faillenot, I. *et al.*, 1999; Shikata, E. *et al.*, 2001). This area might be homologous to monkey cIPS.

1.30.4.2 Parieto-Occipital Cortex/V6

The anterior bank of the parieto-occipital (PO) sulcus of the macaque monkey (classically considered as part of Brodmann's area 19) contains two functionally distinct areas: a ventral, purely visual area, V6, and a dorsal area, V6A, containing visual neurons and neurons related to the control of reaching movements (Colby, C. L. *et al.*, 1988; Galletti, C. *et al.*, 1996; 2005). Macaque V6 contains a topographical representation of the contralateral (both upper and lower) visual field, up to an eccentricity of at least 80° (Galletti, C. *et al.*, 1999). Recent findings suggest that the likely

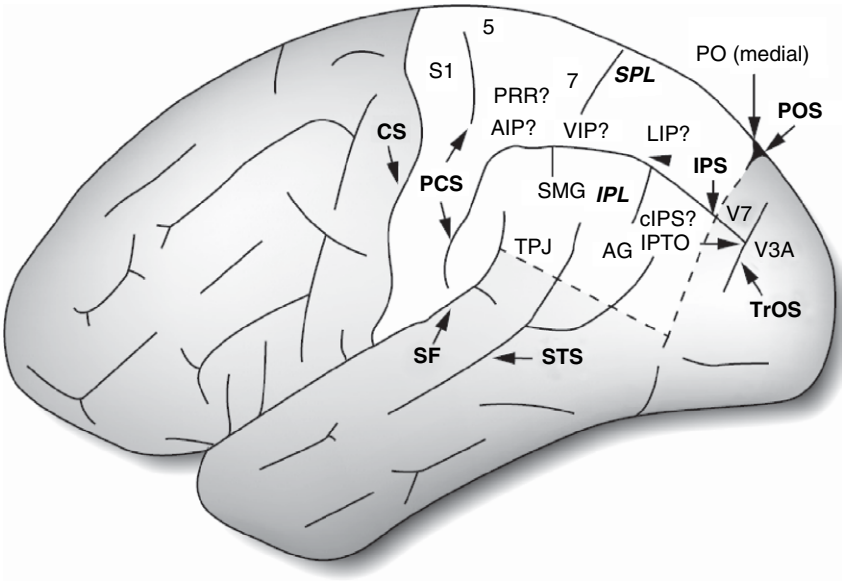

Figure 6 Dorsal stream areas in human parietal lobes. Major sulci, lobules, and functional or anatomical areas have been shown in the lateral view of human brain. Parietal boundaries are based on anatomical landmarks including central sulcus (CS), Sylvian fissure (SF), and parieto-occipital sulcus (POS). The intraparietal sulcus (IPS) divides the parietal lobe into the superior parietal (SPL) and inferior parietal (IPL) lobules. The IPS is located between the transverse occipital sulcus (TrOS near the POS) and the postcentral sulcus (PCS). Several human areas have been proposed to be putative human homologues of monkey areas in the anterior (AIP), ventral (VIP), medial (MIP), lateral (LIP), and caudal (cIPS) sections of the IPS, and also in the parieto-occipital (PO) region. Other areas without clear homologies include the supramarginal (SMG) and angular (AG) gyri, functional areas at the IPS/TrOS junction (IPTO), and the temporo-parietal junction (TPJ). Medial parietal areas have not been well characterized in humans. Adapted from Culham, J. C. and Kanwisher, N. G. 2001. Neuroimaging of cognitive functions in human parietal cortex. Curr. Opin. Neurobiol. 11, 157–163.

human homologue of the macaque V6 is also located in the parieto-occipital sulcus (anteromedial cuneus) (Dechent, P. and Frahm, J., 2003). Human V6 responds strongly to luminance flicker (Portin, K. and Hari, R., 1999; Vanni, S. *et al.*, 2001; Dechent, P. and Frahm, J., 2003). The topography of V6 has not yet been established in humans (Portin, K. and Hari, R., 1999; Dechent, P. and Frahm, J., 2003).

1.30.4.3 Parietal Reach Region

Monkey parietal reach region (PRR) includes both area V6A and the medial intraparietal area (MIP) (Galletti, C. *et al.*, 1997; Snyder, L. H. *et al.*, 1997; Galletti, C. *et al.*, 2003). Neuroimaging studies have also reported activation in the human IPS during reaching and pointing movements (Kertzman, C. *et al.*, 1997; Connolly, J. D. *et al.*, 2000). Reach activity has been reported anterior to saccade activity (Kawashima, R. *et al.*, 1996), whereas pointing-related activation seems to be more medial to a saccade-related region (Connolly, J. D. *et al.*, 2000). A reach-related region in the anterior IPS is modulated by eye position (Baker, J. T. *et al.*, 1999; DeSouza, J. F. X. *et al.*, 2000) and could be the human homologue of the monkey PRR (Andersen, R. A. *et al.*, 1985).

1.30.4.4 Anterior Intraparietal Area

Neurons in monkey anterior intraparietal area (AIP) are involved in fine grasping (Sakata, H. and Taira, M., 1994). The human anterior IPS is also activated during visually guided grasping (Faillenot, I. *et al.*, 1997; Binkofski, F. *et al.*, 1998; Shikata, E. *et al.*, 2003; Culham, J. C. *et al.*, 2003), although grasping activity appears to overlap with reach-related activity. This area is a probable human homologue of monkey AIP. Other studies have reported that this region is also activated by action observation (Iacoboni, M. *et al.*, 1999; Buccino, G. *et al.*, 2001; Muhlau, M. *et al.*, 2005), mental rotation (Bonda, E. *et al.*, 1995), cross-modal processing of object features (Grefkes, C. *et al.*, 2002), tactile manipulation of objects (Binkofski, F. *et al.*, 1999a; 1999b), and even by passive viewing of graspable objects, namely tools (Chao, L. L. and Martin, A., 2000).

1.30.4.5 Ventral Intraparietal Area

Monkey ventral intraparietal area (VIP) responds to motion in any sensory modality (Colby, C. L. *et al.*, 1993; Duhamel, J. R. *et al.*, 1998). Bremmer F. *et al.* (2001) have identified a region in the depth (fundus) of the human IPS that responds multimodally to visual, tactile, and auditory moving stimuli. They propose that this area might be the human equivalent of monkey area VIP. This region is also activated by 3D structure from motion (Orban, G. A. *et al.*, 1999; Vanduffel, W. *et al.*, 2002). In addition, human VIP may play a crucial role in the representation of quantity and number processing (Dehaene, S. *et al.*, 2003; Hubbard, E. M. *et al.*, 2005).

1.30.4.6 Lateral Intraparietal Area

Sereno M. I. *et al.* (2001) have identified a region of the posterior IPS that is thought to be homologous to monkey lateral intraparietal area (LIP) (Colby, C. L. *et al.*, 1996). This region is active when humans make visually guided saccades (Muri, R. M. *et al.*, 1996). Putative LIP contains a retinotopic map of saccade direction (Sereno, M. I. *et al.*, 2001), similar to macaque LIP (Ben Hamed, S. *et al.*, 2001). In addition, recent studies have shown that this region in the IPS is jointly activated by attending, pointing, and making saccades to peripheral targets (Astafiev, S. V. *et al.*, 2003). Another parallel between macaque and human area LIP is the involvement of these areas in spatial updating and representing the spatial location of targets in eye-centered coordinates (Medendorp, W. P. *et al.*, 2003; Merriam, E. P. *et al.*, 2003).

1.30.4.7 Superior Parietal Lobule and Inferior Parietal Lobule

The parietal lobe above the IPS and below the IPS is called superior parietal lobule (SPL) and inferior parietal lobule (IPL), respectively. Human SPL is believed to be homologous to area 7 in macaque cortex (Andersen, R. A., 1988). Human SPL and IPL (including the supramarginal gyrus) along with regions in the IPS, the postcentral sulcus, and the temporo-parietal junction are activated in attention-related tasks (Corbetta, M. *et al.*, 1993; 1998; Wojciulik, E. and Kanwisher, N., 1999; Donner, T. *et al.*, 2000; Corbetta, M. *et al.*, 2000; Hopfinger, J. B. *et al.*, 2000; Perry, R. J. and Zeki, S., 2000; Culham, J. C. *et al.*, 2001). So far, the precise role of these parietal regions in attention is a matter of substantial debate; however, several studies have strengthened the evidence that regions in parietal cortex (particularly SPL and in some cases IPL) are a source of attentional control signals (Kastner, S. *et al.*, 1999;

Shulman, G. L. *et al*., 1999; Corbetta, M., *et al*., 2000; Hopfinger, J. B. *et al*., 2000).

1.30.5 Frontal Areas

Felleman D. J. and Van Essen D. C. (1991) have classified macaque areas 8 (FEF: frontal eye field) and 46 as part of visual cortex. However, little is known about the visual properties of frontal and prefrontal cortical areas in humans. Recently, one study has shown that working memory-related areas in human dorsolateral prefrontal cortex contain a topological map of visual space (Hagler, D. J., Jr. and Sereno, M. I., 2006).

1.30.6 Conclusions

Over the past several decades, the intense and comprehensive study of visual cortical areas in monkeys and other mammals has resulted in what are arguably the best-understood regions of mammalian cortex. This body of work has formed the basis of well-informed models of how sensory information is processed on its way to higher-order integration.

Over most of that time span, very little was known about the workings of visual cortex in humans, except for a few hints from histology and neuropsychology about V1, and a few higher-order visual processing regions. However, with the advent of modern, non-invasive neuroimaging techniques, and with a more systematic comparison of information from macaques and humans, our understanding of human visual cortex is maturing nicely. The next few decades promise to be even more revealing.

In the cerebral cortex the objects of perception are represented by the responses of groups of neurons which are tuned to rather complex combinations of the features that characterize a particular object. This coding strategy is a compromise between the option to represent objects by individual neurons that respond in a highly selective way only to a single object and the option to represent objects by very large assemblies of neurons each of which is tuned to only one of the many elementary features that constitute complex objects. The disadvantage of the first option is that it requires a very large number of representational units and cannot cope with the representation of novel objects. The disadvantage of the second option is that it requires an immense number of connections to assure flexible association of large numbers of neurons in ever changing constellations. Because the number of afferents that can effectively contribute to the selective recruitment of neurons into an assembly is limited by the dynamical range of the neurons, there is an upper limit for the degree of connectedness. Moreover, the two coding strategies differ with respect to processing speed. Less processing time is required to represent objects by individual specialized neurons than by dynamically configurated assemblies because the former can be realized in strictly feed-forward architectures while the latter requires cooperative interactions within reciprocally coupled networks. There is thus a tradeoff between different hardware constraints, versatility, and processing speed.

Analyses of the response properties of neurons encountered at the various levels of the processing hierarchy of sensory systems suggest the following sequence of processing steps. Neurons in the sensory organs encode in their responses very elementary, local properties and qualities of the components of perceptual objects and barely any relations. An exception is the retina of the eye. Unlike most other sensory organs it possesses a complex, multilayered network that permits, first, recombination of signals in convergent feed-forward architectures and, second, extensive lateral interactions that modulate responses in a context-dependent way. Thus, the rate-modulated output of ganglion cells does not only signal the presence of a local property of an object, in this case the brightness and spectral composition of a small part of its surface, but also the neighborhood relations of these particular features. Elaboration of truly feature-specific neurons occurs at the cortical level. As one proceeds along the cortical processing hierarchy, one encounters neurons that respond selectively to increasingly complex constellations of elementary features. It is commonly held that this increased selectivity is achieved by iterative recombination of feed-forward connections from lower- to higher-order neurons. If the thresholds of the respective higher-order neurons are adjusted such that they respond only if the full set of the feeding neurons is simultaneously active, they assume the function of conjunction detectors. Their responses signal not only the presence of certain sets of component features but also the way in which these features are related to each other. The latter information is implicitly encoded in the architecture of feed-forward connections that links selected sets of feeder neurons to higher-order conjunction detectors.

Several theoretical arguments suggest that these binding operations are complemented at each level of processing by additional mechanisms that permit flexible definition of relations among the responses of distributed neurons. Natural scenes, for example, usually contain a large number of different objects, the contours of which may be contiguous or partially occluded. A single border may be shared by several objects and features of occluding surfaces may appear as belonging to the occluded object. This introduces ambiguities that need to be resolved in order to channel appropriately sorted signals to the feed-forward circuits. Without such prior sorting it would be difficult to avoid accidental activation of conjunction specific neurons by features belonging to different objects and hence generation of false conjunctions. Thus, responses to contours belonging to the same object need to be grouped together for further joint processing and they need to be segregated from responses to other objects and the embedding background. This selection of groupable responses has to occur in a context-dependent way and hence requires dynamic routing of signals. Responses evoked by the features of individual objects need to be tagged as related in a way that assures their selective convergence on higher-order neurons. These grouping and routing operations must occur at early levels of the processing hierarchy because successful scene segmentation is a prerequisite for the later identification of individual objects. Context sensitive dynamic definition of relations is also required at the highest levels of processing where neurons are encountered that respond to very complex constellations of features, for example, the various components of a face, the mouth, the eyes, or the nose. This postulate follows from several arguments. First, neurons whose response properties are sufficiently complex and selective to encode only a single perceptual object are rare and seem to exist only for highly overlearned objects or objects of particular behavioral relevance. Second, it is inconceivable that novel objects can be represented by pre-established neurons because the required feed-forward architectures would have to be specified *a priori* to support formation of the appropriate conjunctions. Third, objects that are simultaneously encoded in different sensory modalities elicit responses in several different sensory systems, and these need to be related to each other in order to generate a comprehensive polymodal description of this object. These arguments suggest that objects not representable by individual neurons are encoded by assemblies of distributed neurons, each of which responds only to a particular aspect of the object. However, in assembly coding a relation-defining mechanism is indispensable because responses evoked by the same object need to be tagged as related in order to avoid false conjunctions. Therefore, neurons participating in assemblies need to convey two messages in parallel. First, whether the feature constellation for which they code is present and second, with which other neurons they cooperate in the representation of a particular perceptual object. It is commonly held that the presence of certain features is signaled by increase of discharge rate but it is still a matter of debate how the relatedness of responses is expressed.

2.01.1 Synchrony as Tag of Relatedness

Psychophysical and electrophysiological evidence indicates that attentional mechanisms play an important role in dynamic grouping operations both at the level where scene segmentation is accomplished as well as at higher levels where object identification is thought to occur. However, the mechanisms underlying these relation-defining grouping operations are still poorly understood. One proposal is that attentional mechanisms modulate the discharge rate of neurons and enhance the amplitude of responses to attended features. In this scenario the signature of relatedness is the concomitant enhancement of discharge frequency. Responses selected for combination in convergent feed-forward architectures or the formation of an assembly would be distinguished from all others by their higher discharge frequency. This interpretation has been challenged by the argument that response amplitude may be an ambiguous signature of relatedness because it depends on the match between stimulus and receptive field properties, requires long read-out times, and makes it difficult to segregate assemblies from one another that are simultaneously configurated within the same neuronal network. Therefore, it has been proposed that neurons use in addition to the well-established rate code a temporal code in order to express relations. This latter code should assure that responses tagged as related are processed jointly at subsequent stages, that is, are routed together into the appropriate feed-forward channels and/or are recognizable without ambiguity as originating from cells of the same assembly. Following the discovery that neurons in the primary visual cortex can synchronize their spike discharges with a precision in the millisecond

range, it has been proposed that the synchronization of responses could serve as the required tag of relatedness. One way to select subsets of responses for further joint processing and, thus, for binding them together is to selectively raise their saliency. Most models on the binding function of selective attention are based on such a mechanism but they usually assume that saliency is enhanced by rate increases. However, precise temporal synchronization of spike discharges is an equally efficient means to raise selectively the saliency of neuronal responses. The reason is that synchronized input to target neurons has a much stronger impact than temporally uncoordinated input. Simultaneously arriving excitatory postsynaptic potentials (EPSPs) summate much more effectively than temporally dispersed EPSPs, and this coincidence sensitivity of neurons is further augmented in cortical neurons by a number of specific mechanisms: (1) voltage-gated dendritic sodium and calcium conductances that amplify fast rising depolarizations of large amplitude, (2) the frequency adaptation of synaptic release and postsynaptic receptors which attenuates temporal summation of EPSPs, and (3) a dependence of firing threshold on the rising slope of depolarizations, favoring responses to fast rising depolarizations. These mechanisms increase selectively the impact of synchronous inputs, and they do so with a temporal resolution in the millisecond range. Thus, relations can be defined within narrow temporal windows (<10 ms), and hence different relations can be encoded within the same neuronal network with less ambiguity and in much more rapid alternation than if relations were expressed by joint rate increases.

The proposal that precise temporal synchrony is used as a tag of relatedness in neuronal processing agrees well with the temporal sensitivity of mechanisms supporting synaptic plasticity and Hebbian learning. Known mechanisms of synaptic plasticity exploit temporal correlations among the discharges of input connections and/or the discharges of inputs and those of the postsynaptic target cells. The temporal resolution of the mechanisms – spike timing-dependent plasticity is one example – that classify discharges as synchronous (asynchronous), that is, related (unrelated), and cause synapses to strengthen (weaken) also operate with a precision in the millisecond range. Thus, there is a perfect match between the signatures of relatedness used in signal processing and Hebbian learning. This cannot be otherwise because both processes have to rely on the same relation-defining code to avoid learning of false conjunctions.

2.01.2 The Role of Oscillations in Adjusting Spike Timing

Investigations of response synchronization in the visual system have revealed that precise synchronization of discharges is often associated with an oscillatory patterning of the neuronal responses. Because individual cells tend to skip cycles of these oscillations, they are rarely detectable in the spike trains of single cells but they are readily seen in data representing the responses of large populations of neurons, that is, in multiunit recordings or recordings of local field potentials (LFPs). *In vitro* experiments in cortical slices and simulation studies have in the meantime established causal relations between the two phenomena. The oscillatory patterning of the responses is mainly due to oscillations generated within the various pools of inhibitory interneurons that are coupled both through chemical and electrical synapses and capable of sustaining oscillatory activity patterns in different frequency bands. These oscillatory inhibitory inputs to pyramidal cells veto their discharges during the inhibitory troughs and favor discharges at the depolarizing peaks, thus causing synchrony in firing. These locally synchronized oscillatory responses can become synchronized over large distances due to reciprocal coupling of the oscillatory networks via excitatory corticocortical connections. It follows from this mechanism that the precision with which spikes can be synchronized increases with oscillation frequency. A relation exists also between oscillation frequency and the distance over which synchronization is maintained. Synchronization among remote groups of neurons or among large assemblies of neurons extending across different cortical areas tends to occur at lower oscillation frequencies than synchronization of local clusters of cells. The latter are often synchronized in the gamma-frequency band while long distance synchrony is more often supported by oscillations in the beta, alpha, and theta bands.

In addition to limiting discharges to the depolarizing phase of the oscillation cycle, which increases synchronous firing, the oscillatory modulation of the neurons' membrane potential has a second effect on spike timing that may be as important as the synchronization effect. As mentioned above, network oscillations are associated with rhythmic inhibition of pyramidal cells. Thus, an oscillation cycle consists of two phases: the depolarizing phase, during which the probability to respond to excitatory input increases progressively until the peak of the cycle is reached, and the hyperpolarizing phase, during

which cells are virtually refractory due to the shunting and hyperpolarizing effects of the inhibitory postsynaptic potential (IPSP) barrage. Therefore, weak inputs will be able to evoke spikes only late in the depolarizing phase while strong inputs will elicit discharges already during earlier segments of the depolarizing cycle. It follows that the phase in the oscillation cycle at which a neuron fires will depend on its excitatory drive and the relative phase at which two neurons fire will depend on the relation between their respective excitatory drives. Experimental evidence for this phenomenon of phase precession has been obtained both in the hippocampus and the neocortex. In the visual cortex the relative phase at which two multi-unit activities (MUAs) synchronize with the stimulus-induced gamma oscillations depends on the relative strength with which they are activated: when a stimulus is presented that activates one neuronal group strongly and another weakly, then the more strongly activated group fires slightly earlier in the gamma cycle than the more weakly activated group and vice versa. In view of the growing evidence that the precise timing of individual spikes matters, for example, as in spike timing-dependent plasticity, phase-dependent spike timing could be functionally relevant. As mentioned above, pyramidal cells can only respond within a narrow temporal window when the network engages in oscillations. Furthermore, pyramidal cell firing is a self-terminating process because pyramidal cells strongly excite interneurons and these feed back on the pyramidal cells, curtailing their firing. Thus, if a pyramidal cell does not fire sufficiently early in the gamma cycle, it will not be able to fire at all in that cycle. In other words, in each gamma cycle, there is a race among the pyramidal cells during which the most excited pyramidal cells will compete against the less excited ones. This winner-take-all mechanism could contribute to the selection and context-dependent routing of signals. Moreover, transforming the rate-coded amplitude of input signals into phase-defined spike times could be used very effectively to convert rate codes into temporal codes that, in turn, can then be used for the expression of relations.

Spike latency coding or spike rank order coding has been the core component in a class of computational models that perform object recognition with remarkable speed and computational efficiency. Changes in event-related potentials recorded from the scalp of human subjects asked to decide whether complex visual scenes contained an animal indicate that it takes the visual system as little as 150 ms to reach a decision. Given that it takes already about 50 ms for the image to activate the primary visual cortex, and given that there are multiple synapses between primary visual and inferotemporal cortex, it is highly unlikely that the luminance distribution of the retinal image was assessed solely by evaluating the average firing rates because this would require integration over too long time intervals. The alternative is that brightness values are encoded by the degree of phase precession of the first spikes in the responses and that further computations would be based on the relative spike latencies. Repetition of this coding strategy across the hierarchy of processing stages can support very rapid processing because it requires no temporal integration of rates. A necessary prerequisite for this processing strategy is that the respective next processing stage can decode the phase information. This can be achieved if it receives a copy of the temporal frame, that is, the oscillation cycle. Long-range synchronization of oscillations is now well established allowing distributed spike phase-based computations to operate on the same reference frame.

2.01.3 Feature Specific Binding by Gamma Phase-Dependent Spike Timing in Primary Visual Cortex

During states of focused attention and visual search, the networks in the visual cortex are entrained in internally generated oscillations in the beta and gamma-frequency range prior to any visual stimulation. In this case visual input can arrive at any phase within an ongoing gamma-band oscillation and response onset latencies should be determined not only by stimulus onset but also by the phase of ongoing rhythmic activity. This has been confirmed with recordings in primary visual cortex of anesthetized cats.

The crucial finding was that, across trials, neuronal responses had variable onset latencies with respect to stimulus presentation and part of this variability could be explained by the phase of the ongoing gamma-band activity at which visual stimulation was delivered. When visual stimulation happened to provide thalamic input to cortex during moments when inhibition faded, then latencies were short. Also in this case, the relative timing of spikes contained important information. The data showed that columns coding for related features (same or colinear orientation of contours), that tend to be grouped perceptually, oscillate with zero phase lag. This has the effect that the latencies of the first spikes

of cells responding to groupable features covary and are similar. Hence, these discharges are synchronized right from the beginning. Following the indications that synchronous firing serves to establish relations among distributed responses it has been proposed that this rapid synchronization of first spikes could support rapid feature binding and perceptual grouping.

Further support for this notion comes from multisite recordings in V1 of monkeys trained to freely inspect complex visual scenes. Shortly after the onset of fixation (40–100 ms) one observes a brief burst of highly synchronized high-frequency oscillations in the LFP that are precisely phase-locked across recording sites. These fixation-related oscillations are in turn associated with excess synchronization of spike discharges in the responses to the contours of the scene. As these oscillations occur also when the animal scans a blank screen, they are most likely due to corollary activity that is generated in anticipation of having to process new constellations of features once a new segment of the scene is fixated. In analogy to the effect of the spontaneous oscillations, this self-generated coherent activity could serve the read-out of grouping criteria residing in the network of tangential connection and the translation of these criteria into specific synchronization patterns. The saccade-related oscillations and the associated spike synchronization precede by several tens of milliseconds the peak of the neurons' rate responses which reach a maximum only around 100 ms after the eyes have come to rest. Grouping cues encoded in latency adjustments and spike synchronization would thus be available long before the changes in the neurons' discharge rate can be fully evaluated. Such rapid processing at early stages of the visual system appears desirable given that the animals changed gaze direction on average four to five times in a second. This implies that scene segmentation, the eventual resolution of ambiguities, the selection of signals for binding by convergence, and the subsequent dynamic grouping of neurons into object specific assemblies must have been accomplished within about 200 ms.

It should be noted that such a coding strategy may not apply for all processing streams. It has been demonstrated that spikes can be tightly locked to stimulus transients, for example, in visual area MT, an area of the dorsal visual stream while the above-mentioned synchronization phenomena were observed in recordings from cat area 17 and monkey area V1. Thus, it is conceivable that information conveyed by the magno (y) and the parvo (x) cellular pathways, respectively, is processed differently. The time stamps of external stimuli could be relayed undistortedly by the magnocellular system via rapidly conducting feed-forward loops to preserve precise timing information while the signals conveyed by the parvocellular system could be subject to internal timing mechanisms. In this case synchrony of spikes in the magnocellular system would signal temporal relations between external events while synchrony in the parvocellular system would signal – in the same format – relations between features that lack temporal structure and that are established by internal computations.

2.01.4 Mechanisms of Read-Out

The impact that an EPSP has on an oscillating target cell will depend crucially on the time of arrival relative to the gamma cycle. This time depends essentially on three variables: (1) the time of spike generation in the sending cell relative to its oscillation cycle, (2) the conduction delay between the sending and receiving cell, and (3) the phase relation between the oscillations of the sending and receiving network. Assuming fixed conduction delays, the effective gain of a given connection in oscillating networks can thus be modulated over a wide range (essentially from 0 to maximal) by adjusting the phase relations between the oscillating cell groups, the oscillation frequencies, and the phase at which spikes are emitted. Numerous studies on phase and frequency relations among oscillating cortical networks suggest the existence of mechanisms for the adjustment of phase-specific spike timing, of oscillation frequencies, and of phase relations among oscillating cell populations. Thus, the oscillatory patterning of neuronal activity offers a wide range of options to exploit the temporal domain for the dynamic routing of signals within the rigid network of fixed anatomical connections. This, in turn, can be used to support a large variety of functions that go beyond feature binding and polysensory integration such as sensory–motor coordination, attention-dependent selection of signals, dynamic association of the ever changing contents of working memory, and, through spike timing-dependent plasticity, the formation of long-term memories. All of these functions have been shown to be associated with oscillatory activity, in most cases in the high-frequency range of the beta and gamma band. These high-frequency oscillations appear to be particularly well suited for these functions because there

is a direct relation between the selectivity with which dynamic binding and routing can be accomplished and the oscillation frequency: as the frequency increases, the precision of spike timing increases and at the same time the network becomes more sensitive to small variations in spike timing.

2.01.5 The Duration of Synchronized Events

Early investigations of response synchronization were based mostly on conventional cross-correlation analysis of cell discharges and/or LFPs. This method reliably detects synchronous firing if it is sustained over prolonged periods of time but it fails if synchronous events occur only a few times in a response. Therefore, more sensitive measures have been developed that allow assessment of brief events of coincident firing. One of these methods, the unitary event analysis, uses statistical methods to identify single, nonaccidental incidences of coincident firing, the other (spike-field coherence), evaluates consistent phase relations between the discharges of individual neurons and LFP oscillations. Application of these methods to data obtained from conscious behaving animals has revealed that episodes of synchronized firing are often restricted to short epochs of particular behavioral sequences and may be as short as a few tens of milliseconds. This agrees with measurements of the minimal time required to segment scenes and identify objects. It was estimated that the grouping operations required for scene segmentation and object identification should not take more than 10–20 ms per processing stage. This implies that a substantial amount of information about the accomplished grouping must be encoded in the precise timing relations between individual discharges of distributed neurons. The reason is that not much information can be encoded in variations of discharge rates of individual cells, as they can generate only few spikes within such short time windows.

2.01.6 Synchrony and Feature Binding

Evidence from studies in the visual system suggests that response synchronization may be used throughout all processing stages, from the retina to the highest cortical areas, in order to establish relations among distributed responses, that is, to route responses into the appropriate feed-forward channels for binding by convergence and to tag responses of assembly members as related. In all cases synchronization probability reflects some of the Gestalt criteria that are used for scene segmentation and perceptual grouping. In the retina, ganglion cell responses synchronize with millisecond precision if evoked by continuous contours or coherent objects and there is evidence from studies on the escape response of frogs, that synchronicity of ganglion cell firing is actually carrying behaviorally relevant information. Retinal synchronization is associated with high-frequency oscillations (up to 90 Hz) and based on horizontal interactions within the network of coupled amacrin cells.

In the primary visual cortex synchrony is often associated, especially when it is observed over larger distances, with an oscillatory patterning of spike discharges in the gamma frequency range (30–60 Hz). At this processing stage, synchronization probability correlates well with elementary Gestalt rules. It is enhanced between responses evoked by continuous contours, by contours moving with the same speed in the same direction, by colinearly aligned contour segments, and by contours belonging to the same surface. It is maximal among responses evoked by coherent patterns such as regular gratings, and it is minimal or absent among responses to incoherent stimuli such as random dot patterns. In the cortex, long-distance synchronization of responses is mediated by the network of tangential horizontal connections, and if it occurs across the midline of the visual field, by callosal connections. One of the reasons why synchrony is stronger among responses to continuous or colinearly aligned contours or contours moving in the same direction is the anatomical anisotropy of these tangential connections. Those spanning larger distances connect preferentially columns with similar feature preference. Thus, elementary grouping criteria are implemented in the anisotropies of the network of tangential connections and translated into synchronization probability. In cats, such stimulus-specific synchronization phenomena have been observed both within and across different visual areas, both within and across hemispheres, and between the visual cortex and the superior colliculus. In primates, especially in conscious behaviorally trained animals, multisite recordings have been applied much less frequently and therefore less data are available on response synchronization. However, the results obtained from primary visual cortex closely resemble those obtained from cats – but oscillation frequencies tend to be higher and the distances over which synchrony

is observed tend to be shorter. In the motion sensitive area MT response synchronization was found to reflect the Gestalt rule of common fate which is one of the strongest binding cues for perceptual grouping. Presentation of two spatially overlapping bars moving in different directions led to the formation of two distinct assemblies of neurons whereby those responding to the same contour synchronized their discharges, while those responding to different contours, did not. In the inferior temporal cortex of the ventral processing stream, synchronization probability reflects the binding of neurons into assemblies representing individual objects. Neurons responding to the components of faces (eyes, nose, mouth, etc.) synchronized their responses when the arrangement of these components was such that the animals signaled having recognized a face while they did not synchronize when the components were scrambled or presented in a way that was judged by the animal as incompatible with the appearance of a normal face. Neither in the case of MT nor IT was it possible to distinguish between the various arrangements of the presented stimuli if only the discharge rate of the neurons was evaluated. This is compatible with the interpretation that discharge rate signals the presence of particular features while the correlations among the discharges of neurons indicate how these features are related to each other.

2.01.7 Preattentive versus Attention-Dependent Grouping

Grouping operations based on elementary Gestalt rules and the binding of the stereotyped feature constellations of highly familiar objects can occur preattentively. This automatic, attention-independent grouping is thought to be based on binding by convergence in fixed feedforward architectures. However, several arguments suggest that synchronization may also serve as a mechanism for automatic grouping. The synchronization of retinal responses cannot be influenced by attentional mechanisms as there are no efferent projections capable of conveying the required information. The fact that feature-specific response synchronization is readily observed in anesthetized preparations also suggests that binding through synchrony can occur preattentively. Interestingly (and this may turn out to be a feature distinguishing grouping by convergence from grouping by synchronization) grouping by synchrony – even if preattentive – is highly context dependent while grouping by convergence is not. Despite anesthesia, grouping by synchronization remains sensitive to the global configuration of stimuli. In cat areas 17 and 18 synchronization probability changes when variations in stimulus context require a change in grouping, and this reorganization of synchrony patterns occurs even if stimulus configurations are changed in a way that leaves the stimulus segments appearing within the aperture of the classical receptive fields of the recorded neurons unchanged.

In addition to this evidence for attention-independent grouping by synchrony, more recent results clearly indicate that synchronization is also highly susceptible to top-down, attention-dependent influences and that it plays an important role in attention-dependent response selection and binding. Various measures have been used to assess the influence of selective attention on neuronal synchrony: Correlations among spike discharges, spike-field coherence, correlations in phase locking between oscillatory field potentials, and finally, the amplitude and the phase locking of oscillatory responses in magnetencephalography (MEG) and electroencephalography (EEG) recordings. Because the amplitude of MEG and EEG signals depends to a crucial extent on the synchronicity of large populations of neurons, not only variations in phase locking but also in the power of oscillations can be taken as a measure of synchrony. These data indicate that focusing attention on a particular stimulus or on a particular modality increases the synchrony of responses in the neuronal networks that process the attended stimulus. Again, this enhanced synchronization is associated with and most likely caused by an oscillatory patterning of neuronal activity in the beta and especially in the gamma-frequency range. At the same time one observes a reduction of oscillatory activity in lower frequency bands (alpha, delta). Evidence also indicates that anticipation of a particular stimulus or a motor act is associated with the generation of oscillatory activity in the beta- and gamma-frequency band in cortical areas required for the processing of the stimulus or the execution of the task. For tasks involving sensory discrimination and motor responses this anticipatory synchronization can extend across widely distributed networks of cortical areas. This anticipatory modulation of oscillatory activity is usually not associated with major changes in the discharge activity of neurons, suggesting that it consists mainly of a synchronous pacing of excitability through oscillatory activity generated in the network of inhibitory interneurons. It has been proposed that this subthreshold modulation of excitability facilitates rapid synchronization of responses once stimuli are available, thereby enhancing

transmission across multiple cortical stages. Recent results from MEG studies in human subjects take this proposal one step further and suggest that the anticipatory induction of coherent oscillations across distributed cortical areas and executive structures facilitates selective routing of activity and rapid handshaking among the involved processing stages. However, at present, it is unknown which centers coordinate this attention- and task-dependent modulation. Thalamic nuclei such as the pulvinar, the nuclei of the basal forebrain, and the basal ganglia are candidates for the mediation of synchrony across widely distributed regions of the brain.

2.01.8 Equivalence of Rate Codes and Temporal Codes

In principle, synchronization could be used as an alternative mechanism to rate modulations in order to raise the saliency of responses. Experiments on binocular rivalry support this conjecture. In cat primary visual cortex the responses to the respective perceived stimulus differed from those to the suppressed stimulus because they were more synchronized and not because they were more vigorous. A similar conclusion is suggested by experiments on perceived brightness. If a small grating is superimposed on a large grating, the perceived contrast of the former increases with increasing orientation or phase offset between the two gratings. This effect is closely related to changes of neuronal responses in primary visual cortex. Neurons responding to the small grating increase their discharge rate but not their synchrony with increasing orientation offset while they increase the synchrony of their discharges but not the rate with increasing phase offset. This indicates that the saliency of responses can be enhanced either by increasing the rate or the synchronicity of discharges. The fact that the effects are perceptually indistinguishable illustrates nicely the complementarity of rate codes and temporal codes.

2.01.9 Conclusions

The data reviewed in this chapter suggest that sensory systems exploit two complementary ways to evaluate and represent relations between features of perceptual objects. One strategy consists of the generation of specialized neurons in feed-forward architectures that respond selectively to particular constellations of features. The discharge rate of these neurons encodes both the presence of particular features and the way in which they are related to each other. This coding strategy is fast but can encode only relations defined *a priori* by the convergence patterns of the feed-forward connections. As multisite recordings suggest, there is a second strategy that exploits the precise temporal relations between the discharges of distributed neurons to encode relations. This mechanism permits flexible and context-dependent definition of relations. It exploits the coincidence sensitivity of neurons and uses precise temporal synchronization of discharges as tag of relatedness. Interestingly, the same tag appears to be exploited by the mechanisms mediating use-dependent synaptic plasticity and associative learning. As synchronization enhances the impact of the synchronized responses, it appears to be used not only to define relations among distributed responses but also in a more general way to select responses for further processing, to raise their perceptual saliency, and to support selective routing of activity under the control of attentional mechanisms. Because temporal codes can only be assessed with multisite recordings and because these have a relatively short history, we are still at the beginning of understanding coding strategies based on the dynamic interactions among large numbers of neurons. It may turn out that precise synchronization is only one, albeit a very important signature of the many potentially significant dynamical states. Precisely timed phase offsets and sequences of patterns defined by specific temporal relations are likely to play an equally important role. To analyze these more complex patterns and to examine whether they contain information that can be related to behavior is one of the great challenges in future systems neurobiology.

Glossary

binocular disparity Small differences in retinal position of an object between two eyes.

delayed matching-to-sample task In this task, a cue stimulus is presented at the beginning of a trial. After a delay, the subject is required to choose the cued stimulus from choice stimuli including distractors.

functional magnetic resonance imaging An imaging method to visualize the activated areas in the living brain during performance of cognitive tasks, usually used for human studies.

recognition memory An ability to judge whether an item was recently encountered or not, a type of long-term memory that includes an episodic aspect.

single-unit recording Extracellular recording of a single neuron using a microelectrode inserted in the living brain during performance of cognitive tasks, usually used for animal studies.

tachistoscopic presentation Very brief presentation of visual stimuli, say for 10 ms.

visual agnosia Impairments of visual object recognition usually following brain lesions.

2.02.1 Introduction

Visual object recognition is a goal of visual processing in the primate brain. Although we are able to quickly and effortlessly recognize the objects around us in everyday life, the underlying computation carried out by our visual system is not simple. The visual system must cope with a huge number of objects in the environment under various conditions. A single object can produce different retinal images as a result of differences in viewpoint or illumination, and the object may be obscured or partially occluded. Moreover, object recognition is not complete without linkage to knowledge about what the object is, so that the visual system must compare what it has just analyzed with previously stored memories or typical prototypes formed within the system. Such object recognition or high-level visual processing is thought to be subserved by the inferior temporal (IT) cortex. In this chapter, we argue primarily based on findings in animal studies using macaque monkeys.

2.02.2 Object Vision Pathway

Almost 30 visual areas have been identified in the cerebral cortex of the macaque monkey (Felleman, D. J. and

Van Essen, D. C., 1991; Van Essen, D. C. *et al.*, 1992). These areas comprise two main pathways for visual processing: the ventral pathway leads from the primary visual area (V1) to the IT cortex, while the dorsal pathway leads from V1 to the inferior parietal lobule (Ungerleider, L. G. and Mishkin, M., 1982; Desimone, R. and Ungerleider, L., 1989; Goodale, M. A. and Milner, A. D., 1992; Van Essen, D. C. and Gallant, J. L., 1994). Areas in the ventral pathway are thought to analyze what an object is (object vision pathway), while those of the dorsal pathway are thought to analyze where the object is and where it is going (spatial vision pathway).

The IT cortex is situated at the end of the ventral visual pathway. Via this pathway, retinal images are processed in areas V1, V2, and V4, after which the analyzed information is sent from V4 to the IT cortex (Figure 1(a)). More precisely, the posterior part of the

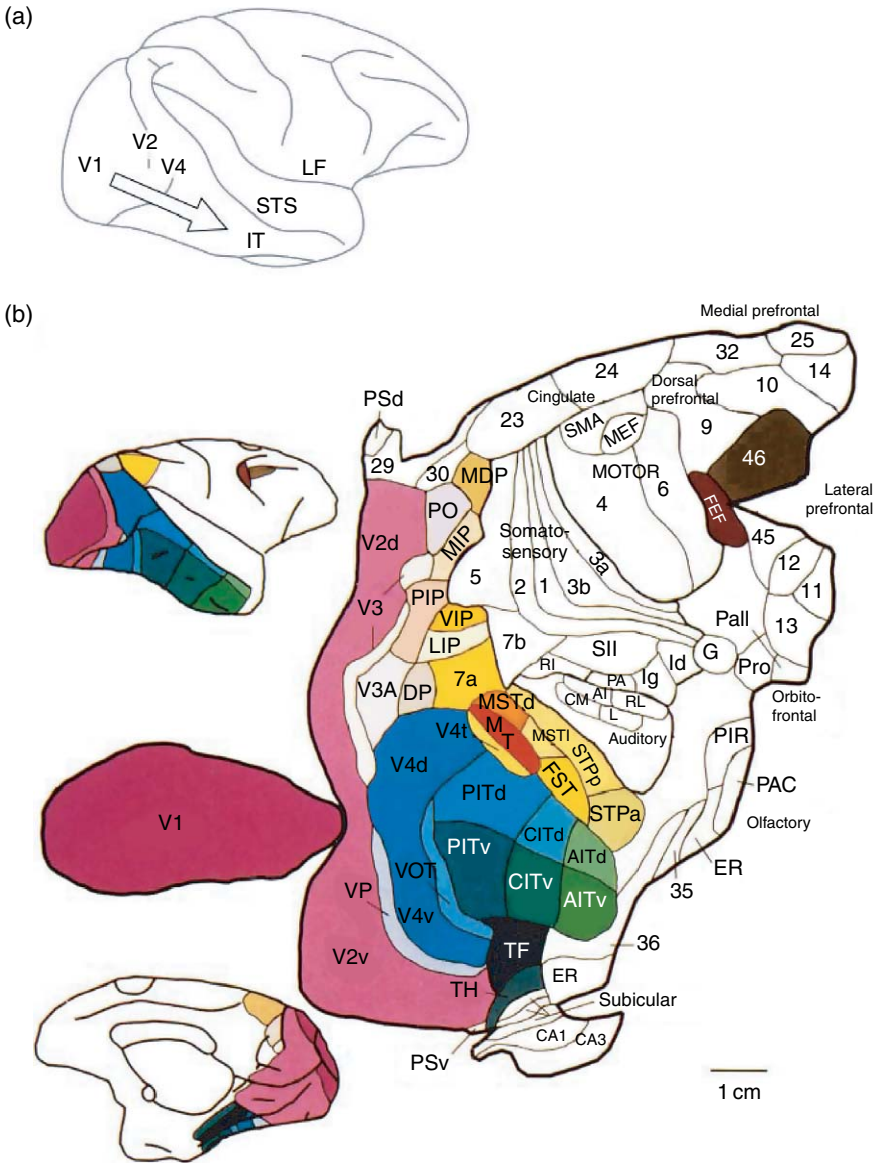

Figure 1 (a) Object vision pathway. A lateral view of a macaque brain is depicted. Arrow: Gross direction of the neuronal processing in the pathway. V1, V2, V4, areas V1, V2, V4; IT, inferior temporal cortex; LF, lateral fissure; STS, superior temporal sulcus. (b) Macaque flattened cortical map of a hemisphere (Felleman, D. J. and Van Essen, D. C., 1991). The IT cortex discussed in this chapter corresponds to areas PITd, PITv, CITd, CITv, AITd, AITv, and 36; area TEO within the IT cortex corresponds to PITd and PITv, while area TE corresponds to CITd, CITv, AITd, and AITv. Insets show lateral and medial views of the hemisphere. Reproduced from Felleman, D. J. and Van Essen, D. C. Distributed hierarchical processing in the primate cerebral cortex. Cereb. Cortex, 1991, Vol. 1, 1–47, by permission of Oxford University Press.

IT cortex (area TEO) receives projections from the prestriate areas V2, V3, and V4, as well as additional sparser projections from areas V3A, V4t, and MT (Distler, C. *et al.*, 1993; a macaque flattened cortical map is shown in Figure 1(b)). Within the IT cortex, the anterolateral part (area TE) receives forward projections from TEO, and the anteroventral part (area 36; A36) receives projections from TE and anterior TEO (Shiwa, T., 1987; Webster, M. J. *et al.*, 1991; Suzuki, W. A. and Amaral, D. G., 1994a; Saleem, K. S. and Tanaka, K., 1996). In addition, there are feedback projections from A36 to TE and TEO, and from TE to TEO (Webster, M. J. *et al.*, 1991; Distler, C. *et al.*, 1993). The IT cortex also receives projections from areas TF and TH in the parahippocampal cortex, from area TG at the temporal pole, and from areas FST at the fundus and STP at the dorsal bank of the superior temporal sulcus (STS; Shiwa, T., 1987; Webster, M. J. *et al.*, 1991; Martin-Elkins, C. L. and Horel, J. A., 1992; Saleem, K. S. *et al.*, 2000). The IT cortex, in turn, projects to the limbic systems, such as the amygdaloid nuclei (Herzog, A. G. and Van Hoesen, G. W., 1976; Iwai, E. and Yukie, M., 1987; Webster, M. J. *et al.*, 1991; McDonald, A. J., 1998) and the hippocampus via the entorhinal cortex (Van Hoesen, G. and Pandya, D. N., 1975; Insausti, R. *et al.*, 1987; Suzuki, W. A. and Amaral, D. G., 1994b; there also are direct routes to the hippocampus; Yukie, M. and Iwai, E., 1988; Rockland, K. S. and Van Hoesen, G. W., 1999). The IT cortex also projects to the ventrolateral and orbital prefrontal cortices (Barbas, H., 1988; Seltzer, B. and Pandya, D. N., 1989; Ungerleider, L. G. *et al.*, 1989; Petrides, M. and Pandya, D. N., 2002). Thus, the anatomical position of the IT cortex can be thought of as an interface between the visual cortices and the limbic systems and frontal lobe.

2.02.3 Effects of Inferior Temporal Damage on Object Recognition

The importance of the IT cortex for visual object recognition is known from both clinical studies in humans and lesion studies in monkeys. Human patients with right temporal lesions show an impaired ability to perform perceptual tasks in which the normal redundancy of visual stimuli is reduced by tachistoscopic presentation (Kimura, D., 1963) or by contrast exaggeration and contour elimination, such as in Mooney's Closure Faces Test (Figure 2(a); Milner, B., 1990). Patients with right temporal lesions also show markedly impaired recognition memory for

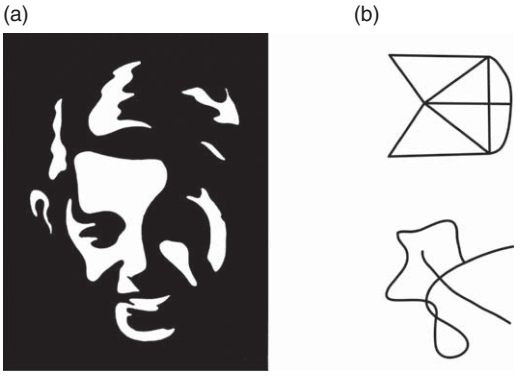

Figure 2 (a) An example face in the Mooney's Closure Faces Test (Milner, B., 1990). The stimuli used in the test are 44 incomplete faces, in which the contrasts are exaggerated and the contours are omitted. Within 30 s, the subjects have to discover the face and indicate the gender and approximate age of the person depicted. Patients who underwent right anterior temporal lobectomy for relief of focal epilepsy exhibited mildly impaired performance on this test. Milner also reported that right temporo-occipital lesions produced the most severe deficit in the test. (b) Examples of abstract line-drawings used in recognition memory tests (Kimura, D., 1963). Patients with right temporal excision performed more poorly on this test than patients with left temporal excision. Their inferior performance was due to the large number of false-positive responses. Upper: geometric design. Lower: nonsense design. (b) Reproduced from Kimura, D. 1963. Right temporal-lobe damage. Perception of unfamiliar stimuli after damage. Arch. Neurol 8, 264–271, the American Medical Association.

complex visual patterns, such as faces (Milner, B., 1968) and abstract line drawings (Figure 2(b); Kimura, D., 1963), which can not be easily encoded verbally. These deficits were found to be unrelated to the extent of hippocampal removal during temporal lobectomy (Milner, B., 1990), suggesting that the temporal neocortex itself may be critically involved in object perception and recognition memory.

Damage to the occipitotemporal area in the human brain often gives rise to certain types of visual agnosia (Humphreys, G. W. and Riddoch, M. J., 1987; Farah, M. J., 2004), including associative visual agnosia and prosopagnosia. Patients with associative visual agnosia have difficulty recognizing objects, which causes their daily life to be severely impaired (Rubens, A. B. and Benson, D. F., 1971; Brown, J. W., 1972; Humphreys, G. W. and Riddoch, M. J., 1987). These patients are not able to recognize objects presented visually until touching them (Figure 3(A)), even though they are able to describe the objects (e.g., a patient described a stethoscope as a long cord with a round thing at the end, while he mistakenly guessed it to be a watch). Furthermore,

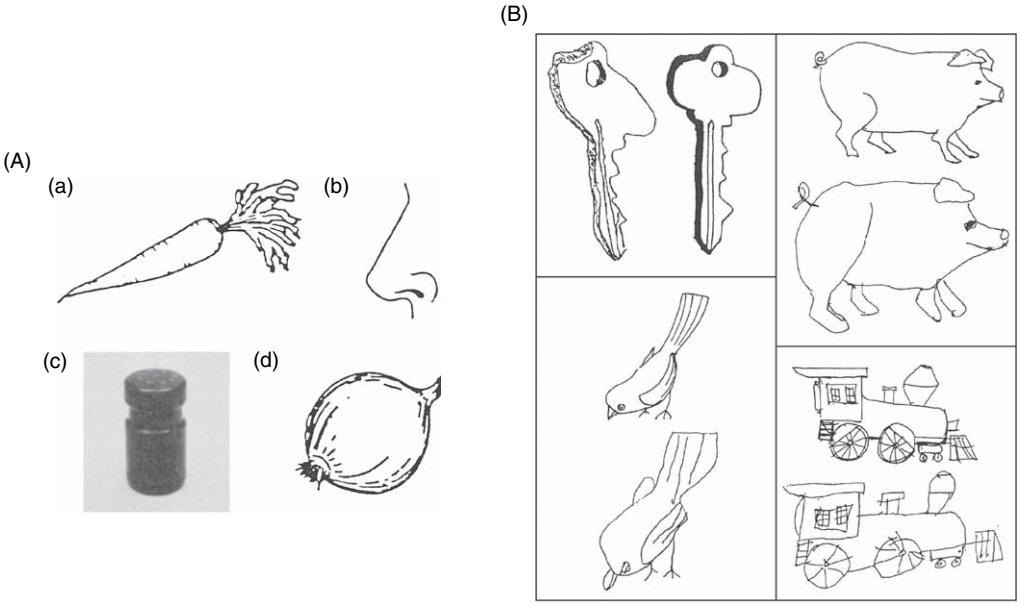

Figure 3 (A) Example of stimuli that an agnosic patient could not correctly identify (Humphreys and Riddoch, 1987). This patient spent a long time coming to his answers and seemed to guess the identity of objects by picking out a salient local feature, not by taking the object as a whole. (a) Line drawing of a carrot (the patient's response, "Some sort of a brush"); (b) line drawing of a nose ("A soup ladle"); (c) photograph of a pepper pot ("A stand containing three separate pans"); (d) line drawing of an onion ("A necklace of sorts"). (B) Copies of line drawings made by an associative visual agnosic (Rubens, A. B. and Benson, D. F., 1971). The line drawings on the right or top of the panels are samples. The patient did not recognize any of the objects in the pictures before or after copying them, although the copying performance was excellent. The patient's comments after copying were as follows: key (upper left), "I still don't know"; pig (upper right), "Could be a dog or any other animal"; bird (lower left), "Could be a beach stump"; locomotive (lower right), "A wagon or a car of some kind, the larger vehicle pulled by the smaller one." It should be noted that the patient drew the pictures rather slowly and in a line-by-line manner (Brown, J. W., 1972), perhaps suggesting impairment of shape perception (Farah, M. J., 2004). (A) Reproduced from Humphreys, G. W. and Riddoch, M. J. 1987. To See but not to See: a Case Study of Visual Agnosia, 1987, Lawrence Erlbaum Associates/Taylor & Francis Group. (B) Reproduced from Rubens, A. B. and Benson, D. F. 1971. Associative visual agnosia. Arch. Neurol. 24, 305–316, the American Medical Association.

without knowing what sample pictures indicate, they copy the pictures accurately (Figure 3(B)). These patients also are able to discriminate objects based on their visual features, but they are not able to classify them based on their category, such as clothing or food (but some patients can retain partial or crude information about the category or superordinate class to which an object belongs; McCarthy, R. A. and Warrington, E. K., 1990). Most patients with this type of agnosia have bilateral lesions, though many well-documented cases have either left or right unilateral occipitotemporal lesions (Levine, D. N., 1982; Farah, M. J., 2004).

Prosopagnosia is the inability to recognize faces, despite intact intellectual ability and even apparently intact visual recognition of most other stimuli (Humphreys, G. W. and Riddoch, M. J., 1987; Farah, M. J., 2004). When looking in a mirror, these patients even misjudge themselves to be an unfamiliar person staring at them. Prosopagnosia is known to often arise with bilateral occipitotemporal damage (Meadows, J. C., 1974; Damasio, A. R. *et al.*, 1982), while it was recently reported that some patients become prosopagnosic after unilateral right hemisphere damage (De Renzi, E. *et al.*, 1994; Wada, Y. and Yamamoto, T., 2001). Prosopagnosia suggests the existence of special neural mechanisms for face recognition. Consistent with that idea are the findings of functional magnetic resonance imaging (fMRI) studies, which revealed that different regions of the human occipitotemporal cortex are activated specifically in response to faces (fusiform face area), places (parahippocampal place area), or body parts (extrastriate body area; Kanwisher, N., 2003; but see also Haxby, J. V., 2004; Grill-Spector, K. *et al.*, 2006).

Another type of visual agnosia, apperceptive agnosia or perceptual categorization deficit, has been also known (Warrington, E. K., 1985; Farah, M. J., 2004). Patients with this disorder are unable to recognize common objects when viewed from unusual perspectives (Warrington, E. K. and Taylor, A. M., 1973) or illuminated from unusual directions (Warrington, E.

K., 1985). Although perceptual constancy across different viewing angles, which is cardinal for object recognition, appears to be impaired in these patients, the disorder probably does not affect object recognition proper but concerns an optional or subsidiary system that may boost the accuracy of object recognition (Warrington, E. K. and James, M., 1988; Farah, M. J., 2004). This is suggested by the fact that these patients are not impaired during usual situations in everyday life, as they are able to recognize objects from different perspectives, so far as they are ordinary. Thus these patients have not lost perceptual constancy across viewing angles. In actual fact, the brain lesions in apperceptive agnosia are not associated with the IT cortex, but with the right inferior parietal lobe (Warrington, E. K. and Taylor, A. M., 1973; McCarthy, R. A. and Warrington, E. K., 1990).

In monkeys, bilateral ablation of the IT cortex causes severe but selective deficits in their ability to learn tasks that require visual recognition of objects (Gross, C. G., 1973; Dean, P., 1976; Mishkin, M., 1982). IT lesions impair the retention of visual discriminations acquired prior to surgery as well as the acquisition of new visual discriminations following surgery (Gross, C. G., 1973). Although extensive and prolonged training might enable monkeys with IT lesions to eventually acquire new visual discriminations, it was revealed that these monkeys are able to solve tasks in abnormal ways. For instance, they may choose the target stimulus based on such visual properties as its position, size, brightness, or other local feature, but not based on its entire shape, *per se* (Iwai, E., 1985).

Monkeys with IT lesions also show an impaired ability to generalize visual stimuli. The normal visual system is able to recognize a given object consistently, even when that object appears in a different visual size (larger or smaller retinal image), in a different orientation (tilted or turned), or under different illumination. In monkeys with lesions of the IT cortex, however, early research revealed impairment of size constancy (Humphrey, N. K. and Weiskrantz, L., 1969; Ungerleider, L. G. *et al.*, 1977). More recently, it was reported that lesions in either the prestriate or anterior IT cortices impaired visual discrimination of objects transformed with respect to size, orientation, or illumination (Figure 4; Weiskrantz, L. and Saunders, R.

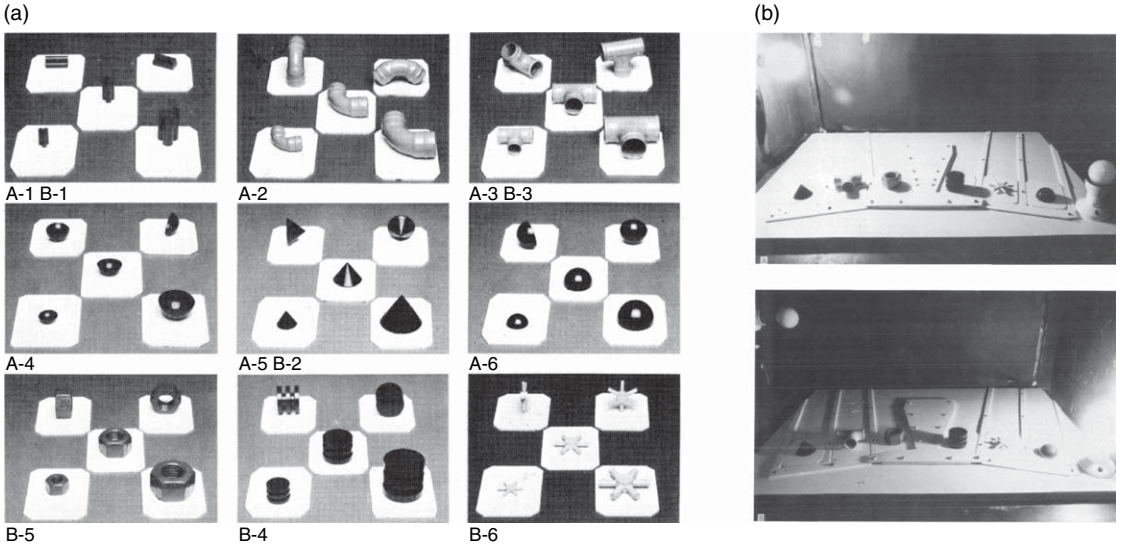

Figure 4 Photographs of example objects used in a visual discrimination task involving transformed objects (Weiskrantz, L. and Saunders, R. C., 1984). (a) Size and orientation transforms. The center object in each panel is the standard training object (not transformed). The two front objects are size transforms, while the back two are orientation transforms. The label for each panel indicates the order in which the transform set was presented to monkeys (see the original article). (b) Illumination transforms, shown with a six-choice apparatus. The illumination transforms were produced by turning off an ordinary overhead lamp in the test setting and turning on a side lamp situated to the left and above the objects (upper panel) or to the right (lower panel). After monkeys with cortical lesions completed discrimination learning of positive targets in the untransformed mode, they were tested in a retention test using untransformed and transformed objects. As compared with the unlesioned monkeys and those with parietal lesions, monkeys with prestriate or inferior temporal lesions showed an impaired ability to initially learn the untransformed objects (which is consistent with previous lesion studies) and then made more errors in the retention test when they were required to choose transformed positive targets. Reproduced from Weiskrantz, L. and Saunders, R. C. Impairments of visual object transforms in monkeys. Brain, 1984, Vol. 107, 1033–1072, by permission of Oxford University Press.

C., 1984). Furthermore, for the prestriate group, the more the lesion extended anteriorly into the IT region, the more severe was the transform deficit. These findings suggest that the more anterior part of the IT cortex may be concerned with formation and storage of an invariant representation, or prototype, of a visual object, which can be accessed during visual discrimination of transformed objects (Weiskrantz, L. and Saunders, R. C., 1984; Weiskrantz, L., 1990).

2.02.4 Stimulus Selectivity of Neurons in the Inferior Temporal Cortex

The response properties of IT neurons have been extensively investigated in electrophysiological studies of monkeys. Early evidence that IT neurons respond to visual stimuli came largely from experiments carried out by Gross and colleagues (Gross, C. G., 1973). They described the heterogeneous response properties of IT neurons as well as their large receptive fields. The visual responses of IT neurons vary depending on several stimulus parameters: direction and speed of movement, size, shape, contrast, and wavelength. The receptive fields of IT neurons cover both visual hemifields and almost always include the fovea: their median size is 418 degrees^2 with an interquartile range of 150–1410 degrees^2 (several recent studies argue that some neurons may have smaller receptive fields that span only a few degrees; Op De Beeck, H. and Vogels, R., 2000; Wang, Y. *et al.*, 2002; DiCarlo, J. J. and Maunsell, J. H., 2003; for a review, Fujita, I., 2002).

More specifically, several studies revealed selective responses within the IT cortex to complex objects, such as hands (Gross, C. G. *et al.*, 1972) and faces (Desimone, R. *et al.*, 1984; Rolls, E. T. and Baylis, G. C., 1986). Face-responsive temporal neurons were first identified in the fundus and the dorsal bank of the STS (Perrett, D. I. *et al.*, 1979; Bruce, C. *et al.*, 1981; Perrett, D. I. *et al.*, 1982; 1984), just adjacent to the IT cortex dorsally. Some of these face-responsive neurons in both areas exhibited different responses to different faces (Perrett, D. I. *et al.*, 1987; Hasselmo, M. E. *et al.*, 1989a; Young, M. P. and Yamane, S., 1992; Leopold, D. A. *et al.*, 2006), which suggests identity coding of faces in those areas. Indeed, the graded face-selective activities in IT neurons could reflect the physical properties of faces (e.g., distance between eyes, width from eyes to a hairline, and so on; Yamane, S. *et al.*, 1988; Young, M. P. and Yamane, S., 1992), or the structural differences between external face stimuli and an internal reference or prototype (Leopold, D. A. *et al.*, 2006). Recent macaque fMRI studies revealed multiple face-responsive areas in the STS (Logothetis, N. K. *et al.*, 1999; Tsao, D. Y. *et al.*, 2003; Pinsk, M. A. *et al.*, 2005). In addition, a later single-unit study demonstrated that most of the neurons in one face-responsive area showed a greater preference for faces than for other categories of objects, such as hands, bodies, and fruit (Figure 5; Tsao, D. Y. *et al.*, 2006).

Other complex two-dimensional figures can also be encoded by IT neurons. Miyashita Y. and Chang H. S. (1988) found anterior temporal cortical neurons that show highly selective responses to computer-generated colored fractal patterns (Miyashita, Y.

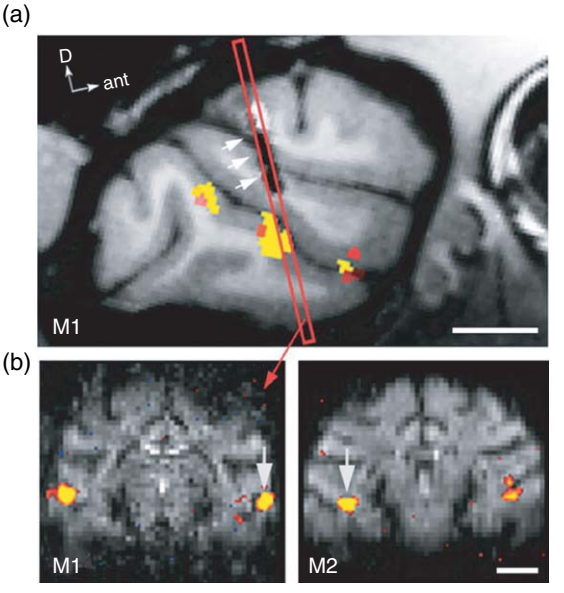

Figure 5 A face-responsive area identified by functional magnetic resonance imaging that was used for subsequent single-unit recording (Tsao, D. Y. *et al.*, 2006). (a) A semisagittal section through the right hemisphere of a monkey (M1) showing three face-selective patches along the superior temporal sulcus. Single-unit recordings in monkeys were performed in the middle patch; the red rectangle indicates a coronal slice through the middle patch. The three white arrows indicate the lesion caused by insertion of a guide tube for recording microelectrodes. (b) MION (monocrystalline iron oxide nanoparticle; a contrast agent) activation overlaid on raw echo-planar coronal images showing the middle face patches in monkeys (left, M1; right, M2). Arrows indicate the patches from which neuronal activity was recorded. The researchers reported that, out of 310 visually responsive neurons recorded from the middle patches in the monkeys, 302 (97%) were face selective. Scale bar = 1 cm. Reproduced from Tsao, D. Y., Freiwald, W. A., Tootell, R. B., and Livingstone, M. S. 2006. A cortical region consisting entirely of face-selective cells. Science 311, 670–674, with permission from the American Association for the Advancement of Science (AAAS).

et al., 1991) in monkeys trained to perform a delayed matching-to-sample (DMS) task. When the visual responses to a large set (usually 100) of fractal patterns were evaluated, it was found that individual neurons commonly responded well to only a small fraction of the stimulus set during the delay period (Figure 6(a)). That the optimal fractal patterns of the individual neurons showed no geometric similarity at all (Figure 6(b); Miyashita, Y., 1988) suggests associative encoding of visual stimuli by IT neurons (see a later section in this chapter).

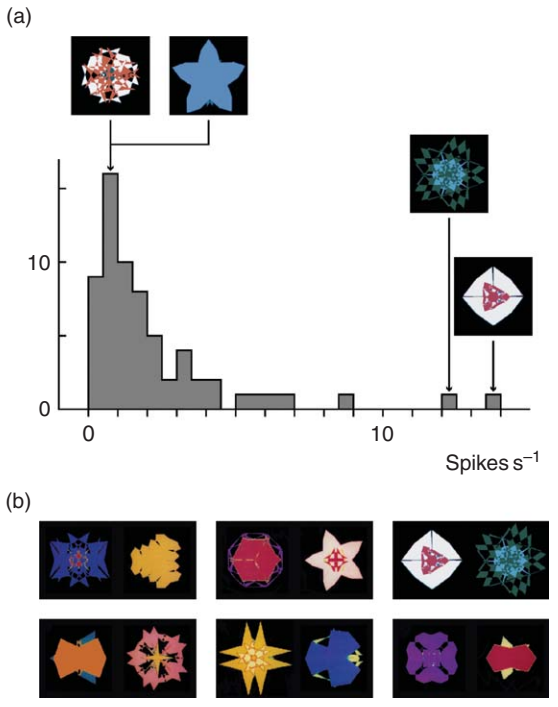

Figure 6 (a) Distribution of responses of a macaque inferior temporal (IT) neuron to 64 different colored fractal patterns (Miyashita, Y. and Chang, H. S., 1988). The monkey performed a delayed matching-to-sample task. For each fractal pattern, the neuronal discharges during the delay periods were averaged over more than four trials in which the fractal pattern was presented as a sample stimulus. The abscissa indicates response strength in terms of spike frequency, and the ordinate indicates the number of fractal patterns. Examples of the fractal patterns used are also shown in the panel with arrows indicating the neuronal responses they elicited. This neuron highly selectively responded to a few optimal stimuli (two examples are on the right-hand side) and only poorly to the others (the examples on the left-hand side). (b) Optimal fractal patterns of six neurons in the IT cortex (Miyashita, Y., 1988). These six pairs of fractal patterns elicited the two strongest delay discharges in six different IT neurons. Note that there is no similarity between the geometric patterns of the two optimal stimuli. (a) Adapted from Miyashita, Y. and Chang, H. S. 1988. Neuronal correlate of pictorial short-term memory in the primate temporal cortex. Nature 331, 68–70, with permission. (b) Adapted from Miyashita, Y. 1988. Neuronal correlate of visual associative long-term memory in the primate temporal cortex. Nature 335, 817–820, with permission.

Tanaka K. *et al.* (1991) used a unique reduction method to investigate the stimulus selectivity of neurons in area TE within the IT cortex. In a stepwise fashion, they removed ineffective or interfering features from an initial effective stimulus to obtain the simplest pattern to which an isolated neuron responded maximally. This reduction method revealed that the critical features to which individual IT neurons respond are more complex than simple bars or disks; they vary from moderately complex shapes, such as a spiny starlike shape or a striped triangle, to combinations of such shapes with color or texture (Figure 7). Moreover, neighboring IT neurons often preferred similar critical features, forming a columnar organization within the cortex (see a later section in this chapter).

Several recent studies showed that the responses of a number of IT neurons could be modulated by binocular disparity (Janssen, P. *et al.*, 1999; 2000; Uka, T. *et al.*, 2000; 2005; for a review, Orban, G. A. *et al.*, 2006). These IT neurons responded to disparity-defined three-dimensional shapes (Janssen, P. *et al.*,

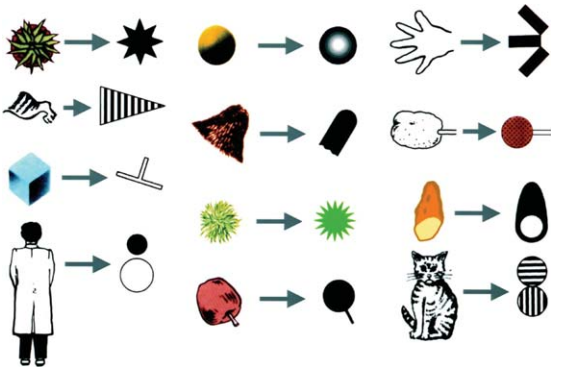

Figure 7 Examples of reductive determination of critical features for 12 neurons (Tanaka, K., 2003). The pictures to the left of the arrows represent the initial effective stimuli and those to the right of the arrows, the critical features determined using the reduction method. An original stimulus could undergo a different reductive process depending on the neuron tested. Note that the process of reducing the original complex stimuli is critically dependent on the experimenter's experience and intuition. Some of the critical features were moderately complex shapes, while others were combinations of such shapes with color or texture. Reproduced from Tanaka, K. Columns for complex visual object features in the inferotemporal cortex: clustering of cells with similar but slightly different stimulus selectivities. Cereb. Cortex, 2003, Vol. 13, 90–99, by permission of Oxford University Press.

1999; 2000) and exhibited selective activity in response to both binocular disparity and shape (Uka, T. *et al.*, 2000; 2005). These findings suggest that binocular disparity is utilized in the IT cortex to analyze and represent three-dimensional objects in the real world. Moreover, they are consistent with studies showing that monkeys with IT lesions have an impaired ability to discriminate between two disks of different physical sizes that are located at different distances from the monkeys (Humphrey, N. K. and Weiskrantz, L., 1969; Ungerleider, L. G. *et al.*, 1977).

2.02.5 Invariance Properties of Inferior Temporal Neurons (Invariance With Respect to Position, Orientation and Size)

The early discovery that IT neurons have large receptive fields was accompanied by the finding that IT neurons show considerable response invariance across retinal positions within those receptive fields (Gross, C. G., 1973). In addition to retinal translation, IT neurons also show varying degrees of response invariance when stimuli are transformed with respect to size, orientation, and other parameters. Several studies have shown that the relative preference of IT neurons for their optimal stimulus over several suboptimal stimuli is preserved over a wide range of stimulus sizes and positions (Sato, T. *et al.*, 1980; Schwartz, E. L. *et al.*, 1983; Tanaka, K. *et al.*, 1991; Lueschow, A. *et al.*, 1994; Ito, M. *et al.*, 1995), although the absolute responses of these neurons only rarely show invariance with respect to stimulus size or position. In addition, the shape selectivity of some IT neurons is maintained across the physical attributes that define the contours of the shape. For instance, the relative preferences of shape-selective neurons are unchanged whether the shapes are determined by differences in luminance, by the motion of dots, or by texture (Sáry, G. *et al.*, 1993; Tanaka, H. *et al.*, 2001). Furthermore, shape selectivity is preserved when visual stimuli are partially occluded (Kovács, G. *et al.*, 1995) or when shading and texture are removed altogether (Kovács, G. *et al.*, 2003). These results above were mainly obtained in the anterior part of the middle temporal gyrus.

In contrast, when IT neurons in the anterior part of inferior temporal gyrus (ITG) were tested in a DMS task using fractal patterns, an even higher degree of invariance was observed (Miyashita Y. and Chang H. S., 1988). Not only the relative stimulus selectivity, but also the absolute response levels, remained the same in the majority of tested neurons when sample pictures were manipulated by reducing their size, rotating them 90° clockwise, or transforming them from color to monochrome (Figure 8). These results, which demonstrate the invariance properties of IT neurons, support the hypothesis that the anterior portion of the IT cortex is involved in storing typical and invariant representations of visual objects (Weiskrantz, L. and Saunders, R. C., 1984; Weiskrantz, L., 1990). A similarly high degree of response invariance also was found in the face neurons located in the STS (Rolls, E. T. and Baylis, G. C., 1986; Perrett, D. I. *et al.*, 1987), which suggests that this region also may be concerned with invariant representation of objects.

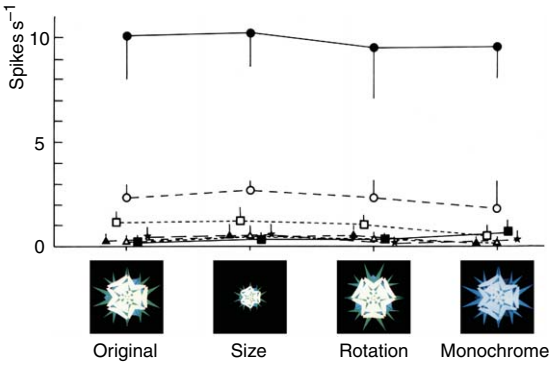

Figure 8 Invariance of the response of an inferior temporal neuron after transformation of the stimulus size, orientation or color (Miyashita, Y. and Chang, H. S., 1988). Original fractal patterns (original) were manipulated in the following way: (1) the size of the patterns was reduced by half (size), (2) the patterns were rotated by 90° in a clockwise direction (rotation), (3) colored patterns were transformed to monochrome by referring to a pseudo-color look up table (monochrome). In the figure, the averaged delay activities are plotted against stimulus transformation. This IT neuron fired during the delay after one particular fractal pattern (closed circles) but not after others (the other markers), irrespective of pattern size, orientation, or color. Similar response invariance also was observed in most of the neurons tested: size invariance was observed in 16 of 19 neurons, orientation invariance in five of seven neurons, and color invariance in 15 of 20 neurons. In the neurons that did not show response invariance, manipulation of the most effective pattern reduced or abolished delay activity. Closed circles: Responses to an original optimal fractal pattern and its transformed patterns; these are shown at the bottom of the figure. Error bars indicate standard deviations for four to 15 trials. The other markers: Responses to original suboptimal fractal patterns and their transformed patterns. Adapted from Miyashita, Y. and Chang, H. S. 1988. Neuronal correlate of pictorial short-term memory in the primate temporal cortex. Nature 331, 68–70, with permission.

2.02.6 Viewpoint-Dependent and Viewpoint-Independent Responses in the Inferior Temporal Cortex

Three-dimensional objects may cast different images on our retina, depending upon the viewing angle. For example, the appearance of a car is quite different when viewed from the front than when viewed from the side: from the front, the windshield, headlights, grille, and bumper stand out; from the side, two wheels, the doors, and the windows stand out. Thus, our perception is viewpoint dependent (front and side views of cars). However, we are able to recognize the object to be a car in both cases, even though the images of the car cast on our retina are quite different. Thus, our cognition is viewpoint independent (it is a car). Probably corresponding to such our perception and cognition, both viewpoint-dependent and -independent responses are found in the macaque IT cortex.

Using different views of visual stimuli, several studies have demonstrated that a large number of IT neurons respond only to limited views of specific objects, and that those neurons exhibit little or no response to nonpreferred objects, irrespective of the viewpoint (Hasselmo, M. E. *et al.*, 1989b; Logothetis, N. K. and Pauls, J., 1995; Logothetis, N. K. *et al.*, 1995; Booth, M. C. and Rolls, E. T., 1998). In contrast, viewpoint-invariant responses to preferred objects, that is, comparable activity favoring an optimal object at all viewing angles, are rarely observed in the IT cortex. It turns out that only a small percentage of neurons exhibit comparable responses to all views of an object, while showing little or no response to other objects, even after extensive discrimination training with the objects (Logothetis, N. K. and Pauls, J., 1995) or after several weeks of familiarization with the objects in the monkeys' home cages (Booth, M. C. and Rolls, E. T., 1998).

The existence of both viewpoint-dependent and viewpoint-independent responses in the IT cortex suggests that viewpoint invariance may have its start there. It would be natural to think that viewpoint invariance develops in the IT cortex through the convergence of viewpoint-dependent responses that are selective for both the object identity and the viewing angle. This is the same scheme that explains the emergence of complex cells from simple cells in V1 (Hubel, D. H. and Wiesel, T. N., 1962). Several proposed models of object recognition indeed include this convergent structure (Riesenhuber, M. and Poggio, T., 2002; Rolls, E. T. and Deco, G., 2002). An object representation that is invariant across viewpoints could be utilized for further processing, such as association with reward or punishment (Rolls, E. T. and Treves, A., 1998) or linkage with a memory about what the object indicates (Miyashita, Y. and Hayashi, T., 2000; Miyashita, Y., 2004). Furthermore, this invariant representation could be associated with prefrontal neuronal representations that are to be processed or manipulated for a task at hand (Goldman-Rakic, P. S., 1987; Hasegawa, I. *et al.*, 1998; Tomita, H. *et al.*, 1999; Fukushima, T. *et al.*, 2004; Ranganath, C. and D'Esposito M., 2005).

How then does the visual system make the convergent connections to realize viewpoint invariance, and how does the system learn that different appearances are of the same object viewed from different angles? A hypothesis comes from the fact that in our experience of the visual world, different views of an object are almost always presented in succession, transformed by the movement of the object or the observer. Therefore, temporal vicinity or successive presentation can be used as a clue to associate together these different images from different viewing angles (Földiák, P., 1991; Miyashita, Y., 1993; Rolls, E. T. and Deco, G., 2002). This hypothesis is experimentally underpinned by an electrophysiological study that showed long-term association of disparate fractal patterns in macaque IT neurons during a DMS task in which fractal samples in a stimulus set were always presented in the same order (Miyashita, Y., 1988). Single-unit recordings after overtraining on the task revealed that IT neurons exhibited correlated responses to sample patterns that were in close proximity to one another within the predetermined stimulus set (Figure 9). Guided by the close temporal proximity of the presented visual images, the IT neurons are thought to have learned associations between the images.

2.02.7 Columnar Organization of the Inferior Temporal Cortex

Similar to the somatosensory (Powell, T. P. and Mountcastle, V. B., 1959) and the primary visual (Hubel, D. H. and Wiesel, T. N., 1968) cortices, the macaque IT cortex is thought to have a columnar organization (Tanaka, K., 2003). The columns are comprised of neurons with similar response properties clustered vertically through the cortex from the pial surface to the white matter (Mountcastle, V. B.,

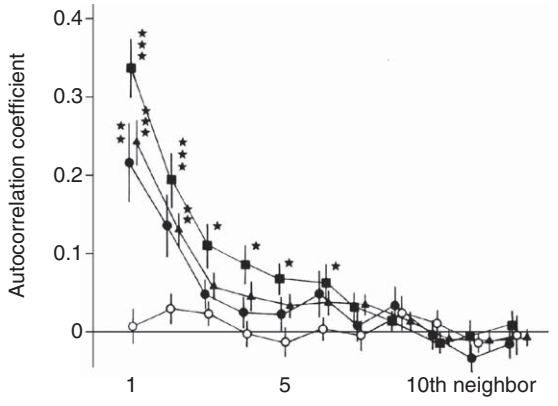

Figure 9 Stimulus–stimulus association among disparate fractal patterns in close proximity along a learned sample set (Miyashita, Y., 1988). Of 206 inferior temporal neurons recorded while monkeys performed a delayed matching-to-sample test, 57 exhibited shape-selective delay discharges. For each of those 57 neurons, autocorrelation coefficients for the responses to learned and new sample sets of fractal patterns were calculated, taking into account the serial position numbers (SPNs) of the sample stimuli, and were plotted against the distance between the SPNs used to calculate the coefficients. The correlation between neuronal responses were high for fractal patterns in close proximity within the learned set, but was nearly zero for both distantly positioned learned patterns and novel patterns. Closed and open circles, average autocorrelation coefficients for the learned and new stimulus sets in 17 neurons that were successfully tested with both sets; closed triangles, coefficients for the learned set in the 57 neurons; closed squares, coefficients for the learned set in the 28 neurons for which the nearest-neighbor correlation for the SPN was significant ($P < 0.05$) according to Kendall's test. Error bars are standard errors. Three vertical asterisks, $P < 0.001$; two vertical asterisks, $P < 0.01$; one asterisk, $P < 0.05$ versus the value for new stimulus list (Kolmogorov-Smirnov test). Reproduced from Miyashita, Y. 1988. Neuronal correlate of visual associative long-term memory in the primate temporal cortex. Nature 335, 817–820, with permission.

1997; Horton, J. C. and Adams, D. L., 2005). Early positive evidence of the columnar organization of the IT cortex came from several electrophysiological studies that suggested the clustering of IT neurons with similar response properties (Gochin, P. M. *et al.*, 1991; Fujita, I. *et al.*, 1992). In one study where functional relationship among IT neurons was investigated using simultaneous recording from multiple microelectrodes, neurons recorded on the same electrode (within about 100 μm) showed more similar stimulus selectivity and were more likely to show correlated discharge than those recorded on different electrodes spaced about 250–500 μm apart (Gochin, P. M. *et al.*, 1991).

In another study, a conventional approach (Powell, T. P. and Mountcastle, V. B., 1959; Hubel, D. H. and Wiesel, T. N., 1968) was used to investigate the columnar organization in the IT cortex (Fujita, I. *et al.*, 1992). The investigators inserted microelectrodes vertically or obliquely into the IT cortex and assessed the response properties of the neurons along the axis of the penetrations. Vertical penetrations revealed that neurons with similar selectivity span most of the cortical layers over distances of 0.7–2.1 mm, which suggests penetrations through single functional columns. In contrast, with oblique penetrations, the widths of clusters showing similar selectivity were shorter (0.2–0.7 mm); the preferred visual feature then changed to a different one after a gap of 0.4–1.0 mm, suggesting penetrations through multiple functional columns.

Recent optical imaging studies have provided further evidence of columnar organization within the IT cortex (Wang, G. *et al.*, 1996; 1998; Tsunoda, K. *et al.*, 2001). Presentation of complex visual stimuli modulated the intrinsic signals at multiple spots within the IT cortex (Figure 10). The size of the affected spots was 0.50 ± 0.13 mm along the longer axis and 0.35 ± 0.09 mm along the shorter axis (Tsunoda, K. *et al.*, 2001). Each spot was specific for a visual feature or a part of an object, and exhibited activation or inactivation in response to a variety of visual stimuli. This suggests that these columnar spots function as basic building blocks to construct neuronal representations of the real objects.

2.02.8 Plasticity of the Stimulus Selectivity of Neurons in the Inferior Temporal Cortex

Many of the studies summarized above show that large numbers of macaque IT neurons respond highly selectively to computer-generated geometrical stimuli (Miyashita, Y. and Chang, H. S., 1988; Sakai, K. and Miyashita, Y., 1991; Logothetis, N. K. *et al.*, 1995), even though these artificial stimuli were completely unfamiliar to the naive monkeys. Since it is highly unlikely that the IT cortex inherently contains neurons that are tuned to these artificial stimuli, the high degree of selectivity of the affected neurons for these computer-generated stimuli is thought to be newly acquired through repeated experience. Consistent with that idea, IT neurons have been shown to respond more selectively to some types of stimuli, including fractal patterns (Miyashita, Y., 1988; Sakai, K. and Miyashita, Y., 1994), batonlike stimuli

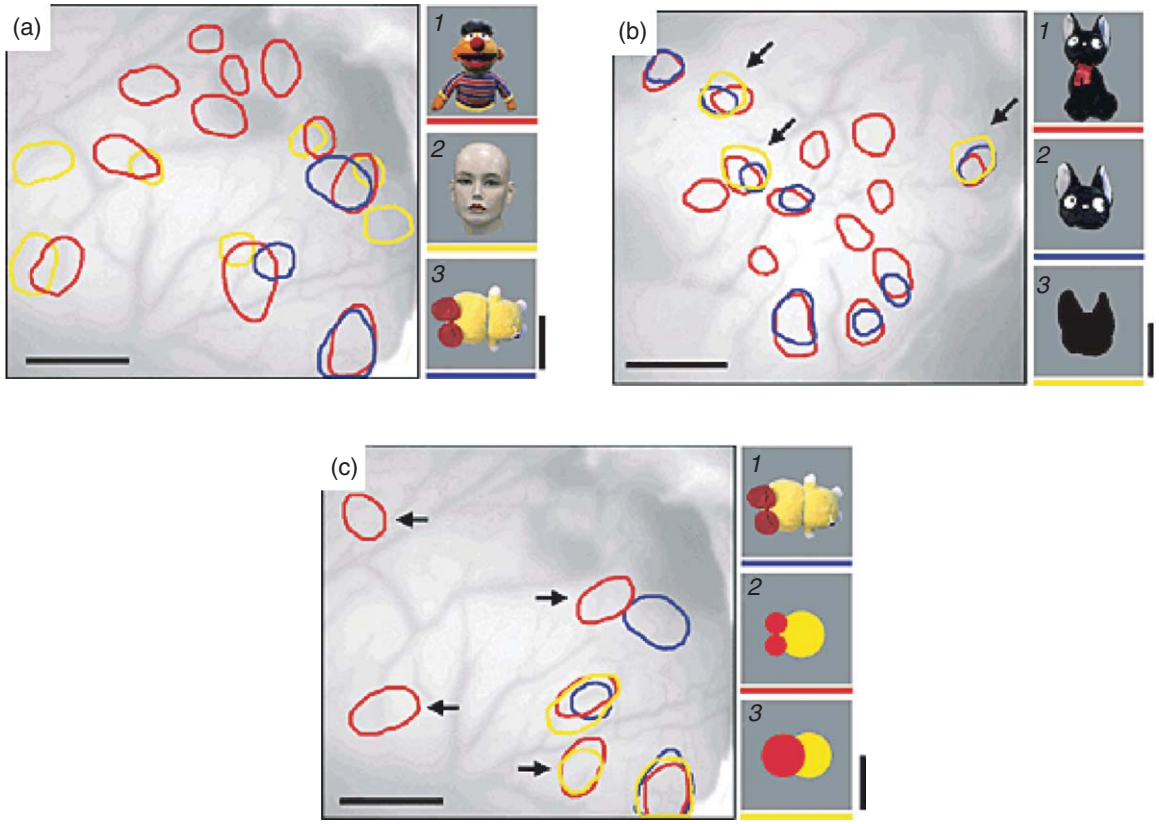

Figure 10 Intrinsic signal imaging in macaque area TE in the inferior temporal (IT) cortex (Tsunoda, K. *et al*., 2001). (a) Spatial patterns of the active spots elicited by three different complex objects. Each complex object elicited several active spots on the dorsal part of area TE in the macaque IT cortex. The outline colors of the spots denote the eliciting objects, which are shown to the right of the panel with colored bars below. Although the spatial patterns of the spots differed, parts of the spots were commonly activated by multiple objects. Activation within the common spots could reflect visual features common to the objects. For instance, the spot in the bottom right corner of the panel could represent a red circle which is common to the objects 1 and 3. (b) Spatial patterns of activation elicited by a complex object and its simplified versions (additive). Some of the spots activated by the initial complex object could not be activated by simplified versions of the object. In this panel, the head of the black cat (object 2) activated a subset of the spots activated by the whole black cat (object 1). Moreover, the silhouette of the head (object 3) activated only three spots (arrows). These results are consistent with the idea that each spot represents a simple visual feature and that a large number of spots are recruited to represent the whole object. (c) Spatial patterns of activation elicited by another object and its simplified versions (suppressive). In this case, some of the spots that were activated by simplified versions of initial complex objects could not be activated by the whole objects. In this panel, object 2 (two small red circles overlapping a large yellow circle) activated four additional spots (arrows) that were not activated by the whole object (object 1). This suggests that some of the spots representing a particular visual feature are suppressed when the feature is embedded within a complex object. Adapted by permission from Macmillan Publishers Ltd: Nature Neuroscience (Tsunoda, K., Yamane, Y., Nishizaki, M. and Tanifuji, M., Complex objects are represented in macaque inferotemporal cortex by the combination of feature columns. Nat Neurosci 4, 832-838, 2001), copyright 2001.

(Baker, C. I. *et al*., 2002), and animal-like stimuli (Freedman, D. J. *et al*., 2006), after training than before training. In addition, the proportion of neurons that selectively respond to moderately complex visual stimuli increases in the IT cortex of trained monkeys (Kobatake, E. *et al*., 1998). Visual experience also increases the similarity of the responses of nearby neurons to trained stimuli (Erickson, C. A. *et al*., 2000). When acquiring such stimulus selectivity through training, it was demonstrated that IT neurons become more specialized for the discrimination of relevant visual features (Sigala, N. and Logothetis, N. K., 2002). This plasticity within the IT cortex could underlie our ability to discriminate among familiar objects, for instance a bird-watcher's ability to distinguish a large number of birds.

Further evidence of plasticity within the IT cortex comes from the finding that some IT neurons can be

tuned to disparate visual images with no geometrical similarity by repeatedly presenting the images in close temporal proximity (Miyashita, Y., 1988), as is described in another section. This suggests that IT neuronal activity learns to reflect the temporal relationship between visual images through experience. A later study also showed that some IT neurons can encode semantic-like relationships between pairs of Fourier descriptor stimuli that are geometrically unrelated and have no other relationship to one another, except that they are operationally associated by the experimenters (Sakai, K. and Miyashita, Y., 1991). In this case, the experimenters trained monkeys on a pair-association (PA) task, which is a well-known neuropsychological test that is widely used to assess dysfunction of the medial temporal lobe memory system in humans (usually, the test is comprised of tens of word pairs). In the visual PA task for monkeys, after one member of a pair is presented as a cue stimulus, the monkeys are required to choose the other member of the pair. Single-unit recordings from the anterior part of the ITG made while the monkeys performed the task revealed that a population of neurons showed comparable or correlated responses to two Fourier descriptors arbitrarily paired in the task (Figure 11) and that they clustered within hot spots in the region. This correlated selectivity to paired visual stimuli develops while the subject is learning the relationship between the stimuli (Messinger, A. *et al.*, 2001). These correlated responses of single neurons could reflect a semantic-like linkage of one visual image to another, and might support object identification in the object vision pathway. Based on the plasticity of the stimulus selectivity in the IT cortex, visual long-term memories could be formed and stored there, probably through the medial temporal lobe memory system (Squire, L. R. and Zola-Morgan, S., 1991; Eichenbaum, H. and Cohen, N. J., 2001; Miyashita, Y., 2004).

2.02.9 Coding Schemes for Object Representation

What neuronal encoding is used in the IT cortex to represent objects? Considering that there are a huge number of natural objects, a one-to-one coding scheme, such as making use of grandmother cells or pontifical cells, would seem unlikely (Barlow, H. B., 1972; Rose, D., 1996). In actual brain, electrophysiological studies have shown that populations of IT neurons can exhibit graded responses to different objects (Komatsu, H. and Ideura, Y., 1993; Young, M. P. and Yamane, S., 1993; Booth, M. C. and Rolls, E. T., 1998). This suggests that the activity patterns of a population of responsive neurons could encode the identities of a variety of objects; this is referred to as sparse population coding (Young, M. P. and Yamane, S., 1992) or distributed encoding (Rolls, E. T. and Treves, A., 1998). Such distributed encoding by a population of neurons is reinforced by information theory (Rolls, E. T. and Treves, A., 1998). In adjoining cortices in the STS, the same coding scheme also has been suggested for face-selective neurons (Baylis, G. C. *et al.*, 1985; Rolls, E. T. and Treves, A., 1998).

Other aspects of neuronal encoding in the IT cortex also have been proposed. As mentioned in another section, the critical features that maximally activate individual IT neurons are moderately complex, but they are still too simple for a single neuron to specify a whole object in the real world (Tanaka, K. *et al.*, 1991). Consequently, multiple neurons with preferences for different visual features would be combined to represent an entire object (Tanaka, K., 1993). Consistent with this idea are the findings of recent optical-imaging studies in area TE of the IT cortex, which demonstrated that in some cases activation spots representing a complex object can be partially activated by components of that object (Figure 10(b); Tsunoda, K. *et al.*, 2001). However, one question raised by this coding scheme is how are objects discriminated in a neuronal representation when they share the same visual features or parts but in a different configuration? Simple convergence of the outputs of the feature-responsive IT neurons, which have moderate position invariance around the fovea, should not be able to discriminate such objects. This simple deduction based on the properties of IT neurons is known as an expression of binding problem in visual object recognition (Malsburg, C. v. d., 1995; Treisman, A., 1999). One possible way to resolve these embarrassing situations is to make use of temporal coding, as has been proposed in models (Malsburg, C. v. d., 1995) and sensory cortices (Singer, W., 1999). In the IT cortex, however, temporal coding was rather unclear, although several studies showed that IT neurons are capable of correlated discharges (Gochin, P. M. *et al.*, 1991; Gawne, T. J. and Richmond, B. J., 1993; Tamura *et al.*, 2004; Aggelopoulos, N. C. *et al.*, 2005). That said, a recent study tackled this issue and succeeded in showing that pairs of IT neurons exhibit more synchronous responses to facelike objects than to nonfacelike objects, both of which are comprised of the same parts (Hirabayashi, T. and Miyashita, Y., 2005).

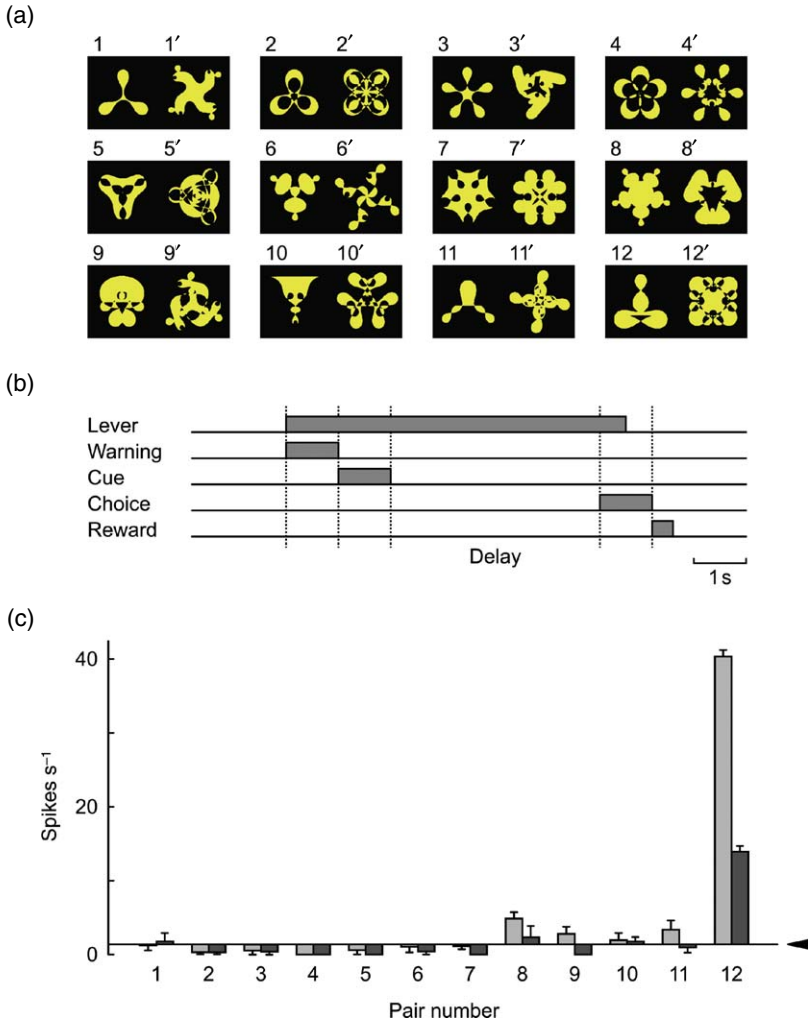

Figure 11 Associative coding of two disparate Fourier descriptors in the macaque anterior inferior temporal (IT) cortex (Sakai, K. and Miyashita, Y., 1991). (a) Twelve pairs of Fourier descriptors (pictures 1 and 1′ to 12 and 12′) were used as stimuli in a visual pair-association (PA) task for monkeys. This task was used to assess visual long-term memory. The monkeys learned to retrieve the other member of the pair when one member was presented as a cue stimulus. (b) Sequence of events in a trial in the visual PA task. Lever: Lever press by the monkey to initiate a new trial. Warning: Green square (1 s). Cue: One of 24 pictures serving as a cue stimulus (1 s). Delay: Green square (4 s). Choice: A choice of two stimuli, the paired associate of the cue and one from a different pair. Reward: Fruit juice reward for correctly touching the associate. (c) Responses of an IT neuron to the 12 pairs of Fourier descriptors. Mean discharge rates for each picture during the cue presentation period relative to the spontaneous discharge rate (denoted by arrowhead) are shown. Cue stimuli are labeled as pair number on the abscissa. For instance, in pair no. 1, the left bar indicates the response to picture 1, the right bar the response to picture 1′. The error bars indicate standard error of the mean. This neuron highly selectively responded to both pictures in pair no. 12, even though pictures 12 and 12′ (a) had no apparent geometrical similarity. Adapted from Sakai, K. and Miyashita, Y. 1991. Neural organization for the long-term memory of paired associates. Nature 354, 152–155, with permission.

Therefore, feature configuration within a whole object could be reflected in spike correlation among a subset of IT neurons.

Alternatively, it has been suggested that configurational information, that is, information about spatial arrangement of local parts, also is carried by IT neurons that have selectivity for complex visual stimuli (e.g., a black circle over a larger white circle, Figure 7, left-bottom). As a consequence, local visual features and their spatial relationship, which together comprise a visual entity, could be represented by a combination of IT neurons (Rolls, E. T. and Treves, A., 1998; Riesenhuber, M. and Poggio, T., 1999; Tanaka, K., 2003; Rousselet, G. A. *et al.*, 2004).

Supporting this is the finding that the responses of some IT neurons to preferred stimuli are influenced by the presence or relative position of neighboring stimuli (Sato, T., 1989; Miller, E. K. *et al.*, 1993; Missal, M. *et al.*, 1999; Aggelopoulos, N. C. and Rolls, E. T., 2005), i.e., the spatial relationship between objects can modulate stimulus-selective activity in IT neurons. Moreover, configurational selectivity was observed among IT neurons preferring stimuli with two local parts. Modifications of stimuli that altered the local parts with respect to color or shape but maintained their spatial relationship did not significantly change neuronal activity, while modification of the spatial relationship of the local parts markedly reduced neuronal activity (Tanaka, K. *et al.*, 1991; Yamane, Y. *et al.*, 2006). Thus, the configurational selectivity incorporated into feature-selective IT neurons may complement the representation of a whole object comprised of multiple local features.

2.02.10 Future Perspectives and Concluding Remarks

The critical role played by the IT cortex in visual object recognition has been well established by a large number of studies in both humans and monkeys. The neurons of the IT cortex, especially those in the anterior ITG, selectively respond to complex visual stimuli and exhibit response invariance with respect to the position, orientation, size, and viewing angle of an object. IT neurons with similar response properties cluster together within the cortex and form a columnar organization in which each column functions as a basic computational block to represent a complex whole object. Some IT neurons can encode novel multiple images through learning based on temporal proximity or on semantic-like relations. This associative property is thought to support the last stage of visual object recognition: identification of what the visual system analyzed along the object vision pathway.

Several different approaches could be used to our further understanding of the mechanism underlying visual object recognition. One possibility is back-engineering. If we could ultimately devise a neural network model that had the same potential for object recognition as a human, the model would provide us with very informative clues as to the details of the neural mechanism functioning in the actual brain. A number of models have been proposed in attempts to simulate some of the functions or behaviors of the visual system. Among those are the neocognitron (Fukushima, K., 1980), a hierarchical model for object recognition (Riesenhuber, M. and Poggio, T., 1999) and VisNet (Rolls, E. T. and Deco, G., 2002).

Another approach is to apply natural scenes to the examination of the visual system. A large number of studies of the IT cortex have focused on the neuronal properties revealed using a few concurrent stimuli with blank surrounds. This is remote from natural vision but is a rational way to control experimental conditions and precisely determine the properties of the responses of IT neurons to visual stimuli. However, the visual system normally works within a natural environment, where objects are cluttered in scenes and the eyes freely move, so that the actual behavior of IT neurons stimulated by natural scenes may differ from that stimulated by one or a few objects with blank surrounds. Indeed, it was recently reported that the responses of IT neurons to effective targets within natural scenes are strongly influenced by whether the subjects noticed the target objects during exploration of the scenes (Sheinberg, D. L. and Logothetis, N. K., 2001). In addition, the receptive fields of IT neurons tend to shrink when natural scenes are viewed (Rolls, E. T. *et al.*, 2003). Investigations making use of natural scenes would likely uncover some aspects of the response properties of IT neurons that are involved in the neuronal representation of cluttered multiple objects within scenes.

A third approach is the use of animal fMRI techniques, which could provide a more plausible means of associating the findings of animal experiments with human cognitive functions (Orban, G. A., 2002), including visual object recognition. Historically, animal experiments using cats and monkeys have provided us with a huge amount of information about the anatomies and functions of the visual cortices (Ungerleider, L. G. and Mishkin, M., 1982; Desimone, R. and Ungerleider, L., 1989; Goodale, M. A. and Milner, A. D., 1992; Van Essen, D. C. and Gallant, J. L., 1994). In contrast, a large number of human fMRI studies have brought extreme progress in the field of cognitive neuroscience for these one and a half decades. Now, fMRI techniques are being applied to animal studies (Stefanacci, L. *et al.*, 1998; Hayashi, T. *et al.*, 1999; Logothetis, N. K. *et al.*, 1999; for a review, Logothetis, N. K., 2003), enabling researchers to compare brain activation in monkeys with that in humans in a search for functional homologs in both

species (Nakahara, K. *et al*., 2002; Tsao, D. Y. *et al*., 2003; Koyama, M. *et al*., 2004). In addition, macroscopic detection of activated cortical regions in animal fMRI experiments enables fMRI-guided neurophysiological investigations (Figure 5; Kanwisher, N., 2006; Tsao, D. Y. *et al*., 2006). To clarify the neuronal mechanisms underlying visual object recognition, it would be greatly informative to record neuronal responses from cortical regions in the monkey that are known to be functionally as well as anatomically homologous to humans. It is anticipated that over the next several years, this last approach will prove to be an especially valuable means of obtaining significant clues to the higher neuronal processing behind visual object recognition, which our visual system so readily and efficiently performs.

Glossary

luminance Luminance refers to how bright something appears to us. It thus includes both the amount of light energy that arrives at the eye, and the sensitivity of the visual system to that light. It is measured in photometric units, such as candela m^{-2}.

contrast Contrast tells us how different is the luminance level at some point in space or time compared to some luminance reference, and is expressed as a ratio, often in percents. Spatial contrast refers to a comparison of some portion of

the visual field with another portion (e.g., the light bars of a grating compared with the dark ones), while temporal contrast refers to a comparison of some luminance level with a previous level at a given point in space. The Michelson contrast is defined as the ratio $C = (L_{max} - L_{min})/(L_{max} + L_{min})$, where L_{max} and L_{min} are the maximal and minimal luminance levels, respectively, and this form is the one used most often in vision science, although the Weber contrast $C = (L_{max} - L_{min})/L_{min}$ is sometimes used as well. In this chapter we shall limit ourselves to luminance contrast, and not discuss chromatic (isoluminant) contrast, in which the comparisons involve quantities that differ in their chromaticity.

contrast gain Contrast gain is the change in response elicited by a change in contrast. In considering neural responses it is the slope of the response versus contrast function (Kaplan, E. and Shapley, R. M., 1986; Croner, L. J. and Kaplan, E., 1995), and has units of impulses s^{-1} $\%^{-1}$ contrast. Contrast gain has also been called responsivity (Enroth-Cugell, C. *et al.*, 1983).

contrast gain control Contrast gain control is an adaptation of the visual system to the prevailing contrast. It has been also called contrast adaptation.

sensitivity Sensitivity is defined as the reciprocal of the minimal quantity of a given stimulus parameter that is required to produce a given response amplitude, typically a minimal (threshold) response. Thus contrast sensitivity is the contrast required to detect a stimulus, and is therefore expressed in units of contrast.

2.03.1 Overview

In this chapter we shall discuss why luminance and contrast are such important concepts in vision science. We shall survey the ways in which these two quantities are encoded and transmitted along the visual pathway from retina to cortex. We shall discuss briefly how these quantities interact in the visual system, what regulates our sensitivity to them, and describe some of the perceptual aspects of luminance and contrast sensitivities. The ways in which contrast sensitivity depends on spatial or temporal frequencies and on other aspects of the visual input are important and large topics, and will be described here only briefly.

2.03.2 Introduction

2.03.2.1 Sensitivity or Response Magnitude?

In general, it is more informative to measure sensitivity as a function of the relevant parameter under investigation (orientation, color, spatial frequency, etc.), rather than response magnitude. If the relationship between response magnitude and contrast is linear (as is the case for the parvocellular – but not the magnocellular – neurons in the primate retina and lateral geniculate nucleus (LGN)), than the two measures provide equivalent information. However, since in most cases that important relationship is nonlinear (showing logarithmic compression, expansive nonlinearity, threshold, or saturation), measuring sensitivity is preferable. In contrast, sensitivity measurements deal only with a limited portion of the dynamic range of the response, often near minimal responses or at threshold, while other measures explore more fully the range of stimuli and responses that the system encounters in the real world.

2.03.2.2 Why are Luminance and Contrast Sensitivities Important?

Luminance and contrast are central to the function of the visual system. Without light (luminance = 0) there can be no vision, and without contrast we can see no spatial or temporal patterns. The ability to respond to luminance is an essential first step in seeing, which makes possible all other visual processes. However, what is really important for making sense of the visual world is not the absolute, steady-state luminance level, but rather its temporal and spatial derivatives, namely, contrast. Contrast sensitivity is thus the beginning of pattern vision, and the mechanisms employed by the visual system to respond to contrast are fundamental for all subsequent visual analysis.

2.03.2.3 Adaptation to Luminance and Contrast

Light intensity at noon can be $\sim 10^{10}$ brighter than it is at midnight, and even in a snapshot of a given scene there is often a wide range of light intensities. This enormous dynamic range presents a special challenge to the visual system, which has several narrow bottlenecks with a rather limited dynamic range, including the synapse between photoreceptors and bipolar cells (Ashmore, J. F. and Falk, G., 1976; Ashmore, J. F. and Copenhagen, D. R., 1983), and the limited firing rates of retinal ganglion cells (RGCs) and cortical neurons. Special adaptive mechanisms are therefore required to reset the operating point, and thus allow the visual system to maintain its differential sensitivity over this huge range, which challenges even the most advanced human-made devices. This is true for both luminance and contrast, although the range of contrasts encountered in nature (especially under water) is typically much more limited than the range of luminance levels. We note that part of the adaptation process to luminance is photochemical (bleaching of the visual pigment), while adaptation to contrast is a neural process.

It is important to emphasize here that vision is a dynamical sense: steady-state measurements of sensitivity fail to account for the observed performance under normal visual situations, in which our gaze saccades rapidly from one fixation point to another. The dynamical influence of previous and neighboring stimuli is profound. However, the topic of adaptation is rather broad, and we shall touch upon it only briefly and incompletely here. One can find a comprehensive summary of luminance adaptation in the review by Shapley R. and Enroth-Cugell C. (1984). Contrast adaptation is discussed in Gardner J. L. *et al.* (2005), and further information can be found Baccus S. A. and Meister M. (2002). We shall touch briefly on contrast adaptation in Section 2.03.2.5.

2.03.2.4 Spatiotemporal Selectivity: The Two-Scales Design

To detect and respond to spatial or temporal contrast, the brain needs to compare the inputs from two or more points in space or time. Typically, one of the quantities that are being compared is some (weighted) average over space or time, while the other reflects a more restricted range of space or time. This two-scale strategy endows the detector with spatial or temporal selectivity: it responds best to some intermediate rate of change, and the response to changes at higher and lower rates is significantly lower. This is illustrated in Figure 1, in which the abscissa is labeled frequency, and could refer to either spatial or temporal frequency. In Figure 1 the inhibition subtracts from the effects of excitation, as in Rodieck's Difference of Gaussians (DOG) receptive field model (Rodieck, R. W., 1965). The mechanism sketched in Figure 1 is a linear one, but nonlinearities can alter the tuning (Shapley, R. M. and Victor, J. D., 1978).

The averaging of inputs across space or time allows the system to reject slow changes or gradients, and this rejection amounts to high-pass filtering or differentiation. The limitations imposed on the fine-scale component by optics, neural connectivity, or speed of reaction, bring about an unavoidable integration (low-pass filtering), which limits the performance at the high end of the frequency spectrum. Together, the high-pass and low-pass filters combine to form the band-pass filter shown in Figure 1. This two-scale antagonistic strategy is ubiquitous in the brain, and can be found in the retina, skin, ear, and visual cortex (Kuffler, S. W., 1953; Ratliff, F., 1965; von Békésy, G., 1967; Srinivasan, M. V. *et al.*, 1982; Somers, D. C. *et al.*, 1995). A more comprehensive, theoretical treatment of the way contrast signals and noise are processed and propagated in a (linear) neural network, can be found in Watson A. B. (1992) .

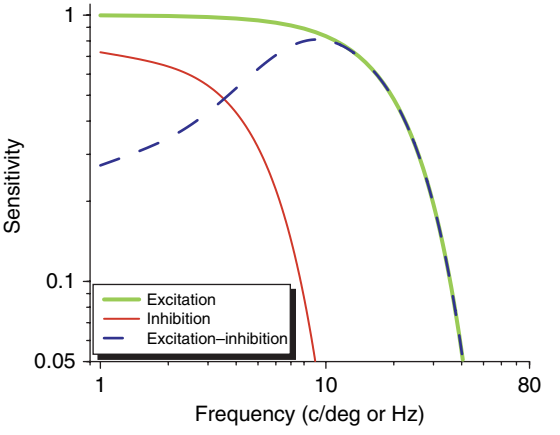

Figure 1 Spatial or temporal selectivity (dashed line) results from the antagonistic interplay of two processes that have very different spatial or temporal resolutions (scales), such as the center and surround of the receptive fields of retinal ganglion cells (Rodieck, R. W., 1965; Enroth-Cugell, C. and Robson, J. G., 1966). Note that both axes are logarithmic.

2.03.3 Physiological Aspects

2.03.3.1 Retina

The computations of both luminance and contrast begin in the retina, and reflect the spatiotemporal organization of the receptive field of each retinal neuron, that portion of the visual world to which each neuron is responsible (Hartline, H. K., 1940). The results of these computations are communicated to subsequent visual stages by the neural discharge of the RGCs.

2.03.3.1.1 Distal retina

The spectral sensitivity of the visual pigment in each retinal photoreceptor determines the probability that a photon of a given wavelength (energy) will be absorbed, and be given the chance to be converted into a neural signal. The luminosity function results from the convergence of the signals originating simultaneously in the various types of photoreceptors, and is therefore different from the spectral sensitivity function of any single class of photoreceptors.

A photoreceptor can respond only to temporal contrast, but not to spatial one, since spatial contrast requires a neural computation that compares the luminance at point A with that at point B. All such computations are, therefore, postreceptoral. (There are junctions among neighboring photoreceptors. However, they are all electrical (and therefore positive) and they appear to contribute very little to the receptors' signals; Schneeweis, D. M. and Schnapf, J. L., 1999.)

The horizontal cells, with their wide ranging dendritic trees, are an essential element of the antagonistic center-surround organization of bipolar and ganglion cells in the retina (Kuffler, S. W., 1953; Werblin, F. S. and Dowling, J. E., 1969). This organization, which pits the narrow center against the broad surround, is essential for the analysis of spatial contrast: it tunes each cell to respond best to spots of a particular size, or, equivalently, to some limited range of spatial frequencies. Some amacrine cells contribute to this tuning process by adding a second contribution to the surround component (Cook, P. B. and McReynolds, J. S., 1998; Kaplan, E. and Benardete, E., 2001).

2.03.3.1.2 Retinal ganglion cells

2.03.3.1.2.(i) Luminance The discharge of the RGCs is an encoded summary of all the processing done by the retina, and thus the effects of the luminance and contrast of the visual scene are embedded in that discharge.

The average, ambient luminance is registered only weakly in the discharge of most RGCs, except when the luminance changes relatively rapidly, when the change can modulate the discharge temporarily. In general, the center-surround antagonistic organization of receptive fields, together with the adapting mechanisms in the retina, keep the maintained discharge of the RGCs more or less constant over time, so that only a limited band of spatial and temporal frequencies of luminance modulation are allowed to influence the firing rate (Figure 1).

Although luxotonic units (neurons that can encode light intensity over a wide luminance range) have been reported in invertebrates (Kaplan, E. and Barlow, R. B., 1975) and in lower vertebrates (Yang, J. *et al.*, 2005), the situation in mammals is more complex, since most RGCs can vary their discharge over only a limited luminance range.

There are, however, some (rare) luminance units (Barlow, H. B. and Levick, W. R., 1969), which can change their maintained discharge monotonically over several log units of stimulus intensity. These might correspond to the recently discovered melanopsin-containing ganglion cells (Berson, D., 2003), which (in the monkey) change their maintained discharge over 8 log units of intensity, utilizing input from rods for scotopic (dim) light levels, and cone input plus their intrinsic melanopsin to respond to higher light levels (Dacey, D. M. *et al.*, 2005). They are involved in the regulation of the circadian rhythm, but since they also project to the LGN (among other targets), the information they provide is likely to be available to the visual cortex, and thus could contribute to the perception of luminance. Their influence on cortical physiology has not yet been explored.

2.03.3.1.2.(ii) Contrast Since contrast is what allows us to see patterns, the dependence of the discharge of visual neurons on it is of paramount importance, and this topic has, therefore, been investigated thoroughly. In general, it appears that the larger the receptive field center, the greater is the contrast gain (Kaplan, E. and Shapley, R. M., 1986; Croner, L. J. and Kaplan, E., 1995). Since the RGCs that project to the magnocellular layers (M cells) are larger than those that project to the parvocellular layers (P cells) at any given retinal eccentricity, they are also much more sensitive to luminance contrast (Kaplan, E. and Shapley, R. M., 1986): their contrast gain is higher. Because the maximum firing

rate of neurons is limited, M cells begin to saturate at much lower contrast than do the P cells, which show little or no sign of saturation at any contrast below 100%. The response versus contrast functions of both M and P cells are well fitted by the Hill equation (named after the English muscle physiologist A. V. Hill, who derived it empirically to describe the binding of oxygen to hemoglobin. The Michaelis–Menten equation of enzyme kinetics is a special case of the Hill equation, for which $n = 1$. In vision science this equation is sometimes referred to as the Naka–Rushton equation (Naka, K. I. and Rushton, W. A. H., 1966), or the hyperbolic tangent function):

$$R = R_{\max} \times C^n / \left(C^n + C_{50}^n\right) \quad [1]$$

in which R is the response, C is contrast, and C_{50} is the contrast at which the response reaches half its maximal amplitude, $R_{\max}$. For RGCs (and LGN cells), n is typically ~1. In the primate, the response of M cells reaches half $R_{\max}$ around 14% contrast, while the P cells' response shows almost no saturation (see figure 1 in Chapter The P, M and K Streams of the Primate Visual System: What Do They Do for Vision?).

Several other functions have been used to fit response versus contrast functions, but all share the basic characteristics of the Hill function: they are sigmoidal, with a steepening slope at low contrasts (an expansive nonlinearity), and a decreasing slope at higher contrasts (a compressive nonlinearity). These two end regions of the curve are connected by a more or less linear middle portion.

Luminance exerts a profound influence on the response to contrast, as expected from Weber's law (see Section 2.03.2.7): as luminance level increases, so does contrast gain (Purpura, K. *et al.*, 1988), at least in the scotopic–mesopic range. At very high luminance levels the effect on contrast gain becomes smaller. It is unclear how fast this adjustment takes place, but it is (at least in part) a neural process, rather than an effect of bleaching of visual pigments, and therefore it is likely to be fast.

2.03.3.2 Lateral Geniculate Nucleus

The responses of LGN neurons to changes in luminance and contrast are rather similar to those of their main excitatory input, the RGCs. In that respect, LGN neurons do function like relay cells, which transmit to the visual cortex the messages delivered to them by the RGCs, with only minor modifications due to dynamical differences and a stronger inhibitory (suppressive) surround (Hubel, D. H. and Wiesel, T. N., 1961; Levick, W. R. *et al.*, 1972; Kaplan, E. *et al.*, 1993; Bonin, V. *et al.*, 2005). A more complete description of how the response of LGN neurons in primates changes with spatial or temporal contrast can be found in two early studies (Kaplan, E. and Shapley, R. M., 1982; Derrington, A. M. and Lennie, P., 1984), and new information about LGN adaptation to luminance and contrast is reported in Mante V. *et al.* (2005), and summarized in Section 2.03.2.5.

2.03.3.3 Visual Cortex

2.03.3.3.1 Luminance

Most cortical neurons require a spatial pattern to be driven effectively, but approximately 25% of cortical units in primates do show luxotonic behavior (Kayama, Y. *et al.*, 1979) under Ganzfeld (diffuse, full field) stimulation. Some are photergic (respond to increased luminance), while the others are scotergic (respond to decreased luminance level). Other units are slowly adapting, namely: they respond temporarily to changes in luminance, but return gradually to their previous firing rate. Curiously, the luxotonic units are rather susceptible to the effects of anesthesia. Whether these neurons receive input from the melatonin-containing light sensitive RGCs has not yet been established. It is not known whether the neural mechanisms that provide information about the overall illumination are the same ones that tell us how bright an object (or a patterned stimulus) is.

A recent study used optical imaging to explore the representation of luminance in the primate cortex, and reported that the thin cytochrome oxydase stripes of V2 contain specialized regions that represent increments and decrements of luminance by the amplitude of their response to such luminance changes (Wang, K. H. *et al.*, 2006). These regions were of two complementary types: one responding to luminance increments, while the other responded to decrements. The input and output of these regions are yet to be determined.

2.03.3.3.2 Contrast

2.03.3.3.2.(i) Single units Visual cortex: one might expect stimulus contrast to be related to the firing rate of cortical neurons, with higher contrasts eliciting higher firing rates. This is, indeed, the case for many cells and many stimuli (e.g., Tolhurst, D. J.

et al., 1981; Albrecht, D. G. and Hamilton, D. B., 1982; Edwards, D. P. *et al.*, 1995). However, firing rate is not the only possible code of encoding contrast in the cortex. For example, Optican L. M. and Richmond B. J. (1987) reported that the temporal firing patterns of neurons in interior temporal cortex of alert monkeys contained information about both the luminance and the contrast of the stimulus. More recently, Reich D. *et al.* (2001) found that the temporal structure of the spike trains of neurons in primate V1 carried as much or more contrast-related information as did the mean firing rate, and that the temporally coded information was manifested most strongly in the latency to response onset. Other aspects of the responses (the transient, tonic, and off components) contributed relatively little additional information. Their results also showed that temporal coding can be used to distinguish subtle contrast differences, while firing rates were useful for coarser discriminations. This suggests that the temporal structure of neurons' responses could extend the dynamic range for contrast encoding in the primate visual system.

A thorough investigation of the dependence of cortical responses on stimulus contrast in mammals has been conducted by D. Albrecht, W. Geisler and their colleagues (Albrecht, D. G. and Hamilton, D. B., 1982; Albrecht, D. G. *et al.*, 1984; Albrecht, D. G. and Geisler, W. S., 1994). In general, most cortical neurons follow the Hill function (eqn. [1]) quite faithfully. On average, the exponent $n = 3$ (± 1.4), and $C_{50} = 25\%$ ($\pm 25\%$). If the stimulus is not the optimal one (e.g., a spot that is offset from the receptive field center, or a grating positioned in a suboptimal position on the receptive field), only the response amplitude is affected. The Hill function still applies for these suboptimal stimuli, but requires a change of scale (Albrecht, D. G. *et al.*, 2002).

The fact that the exponent (n) is much higher in cortex than in LGN or RGCs reflects the much narrower input range of cortical units, which typically go from threshold to saturation over a limited contrast range. The steep response versus contrast functions must be shifted along the contrast range to a new location as the ambient contrast changes. That is the business of contrast adaptation or contrast gain control (Ohzawa, I. *et al.*, 1985; see Section 2.03.2.5).

Because LGN magnocellular cells have a higher contrast gain than do parvocellular cells (Kaplan, E. and Shapley, R. M., 1986), and because the magnocellular and parvocellular inputs to the cortex are segregated, at least at the input layers (Blasdel, G. G. and Lund, J. S., 1983), it is possible to identify, physiologically, the M and P inputs to the cortex (Hawken, M. J. and Parker, A. J., 1984; Hawken, M. J. *et al.*, 1988; Edwards, D. P. *et al.*, 1995).

Response variability: it is worth noting that, like the response amplitude, the variability of the cortical response also increases with stimulus contrast, unlike what is seen in RGCs and LGN neurons (Tolhurst, D. J. *et al.*, 1981; Edwards, D. P. *et al.*, 1995).

2.03.3.3.3 Other measures of cortical activity

2.03.3.3.3.(i) Visual-evoked potentials Visual-evoked potentials (VEPs), which are recorded noninvasively from the unopened skull, reflect the activity of numerous cortical neurons. Nevertheless, the response versus contrast that one obtains in such a recording follows the same Hill function (eqn. [1]) that describes the responses of individual cells (Langheinrich, T. *et al.*, 2000). The exponent found was similar to what is found in single cells, although the C_{50} value was considerably higher. A recent study was able to relate the VEP responses elicited by multifocal stimulation in human to the response versus contrast functions recorded from individual neurons in monkey visual cortex, and show that, with some caveats, the VEP reflects a simple sum of the individual responses of the underlying neurons (Hood, D. C. *et al.*, 2006).

When nonlinear components of the VEP response are analyzed, it is possible to detect the distinct signatures of the magnocellular and parvocellular inputs to the cortex (Klistorner, A. *et al.*, 1997), namely the high contrast gain of the magnocellular cells at low contrast and the near-linear increase of parvocellular response with contrast (Kaplan, E. and Shapley, R. M., 1986).

2.03.3.3.3.(ii) Functional magnetic resonance imaging Like VEPs, the blood oxygen level detection (BOLD) response of functional magnetic resonance imaging (fMRI) obeys a modified version of Hill's function, with an added constant to the exponent of the numerator (Demb, J. B. *et al.*, 1997; Boynton, G. M. *et al.*, 1999). A recent study found that contrast adaptation resets the operating point of the response versus contrast function around the ambient contrast of the stimulus in areas V1, V2, and V3 of the human visual cortex (see below). Area hV4, in contrast, seems to rectify the contrast signal, and produces positive responses that ignore the sign of the contrast (Gardner, J. L. *et al.*, 2005). The

adjustment of the contrast gain took ~15 s. It is worth noting that these fMRI data from conscious humans are consistent with the electrophysiological results obtained from anesthetized cats and monkeys (Albrecht, D. G. and Hamilton, D. B., 1982; Ohzawa, I. *et al.*, 1985).

2.03.3.4 Contrast Gain

As mentioned above, contrast gain is the slope of the response versus contrast function, and has units of impulses s^{-1} $\%^{-1}$ contrast. In RGC and LGN neurons it is closely related to the size of the receptive field center, the region over which the cell integrates its dominant visual input (Croner, L. J. and Kaplan, E., 1995), and which determines its state of light adaptation (Enroth-Cugell, C. and Shapley, R. M., 1973). For cortical neurons, other mechanisms, such as input from the nonclassical receptive field (which, by definition, represents a nonlinear mechanism; the nonclassical receptive field is an area that extends beyond the boundaries of the classical receptive field, which, when stimulated alone, elicits no response, but in which such stimulation alters the responses to stimuli falling inside the boundaries of the classical receptive field), have a significant influence on the contrast gain. Some of these nonlinear effects, which are prominent in the cortex, originate – at least in part – in the retina (McIlwain, J. T., 1966; Krüger, J. and Fischer, B., 1973) and the LGN (Girardin, C. C. *et al.*, 2002).

2.03.3.5 Contrast Gain Control

2.03.3.5.1 General considerations

In order to squeeze the large dynamic range of the visual world through the narrow bottlenecks of its neural machinery, the visual system must adapt not only to the ambient luminance (see Section 2.03.2.7), but also to contrast. The topic of adaptation to ambient and dynamic contrast is a large and important one, and much recent experimental and theoretical work has been devoted to it, especially in connection with cortical mechanisms. It is described here only briefly, and a more complete discussion can be found in Section 2.03.1.3.

In general, the adapting mechanisms shape the spatiotemporal transfer function of the neurons at a particular level (retina, LGN, or cortex) in such a way that, as contrast (or luminance) increases, the transfer functions become more selective: sensitivity to low spatial and temporal frequencies decreases, while sensitivity to intermediate and high frequencies is either unaffected or increased, and the phase of the response is shifted. Thus the term contrast gain control is somewhat misleading, because this adaptation mechanism affects not only the gain, but also the temporal properties of the visual system (time constants and phase lags). This process can be accomplished either by linear means (e.g., subtraction, as in the DOG model of Rodieck), or by nonlinear processes, in which the response at a given frequency is divided or multiplied by some function of luminance or contrast.

Because the characteristics of the visual environment can change rapidly or slowly, the visual system has evolved several adapting mechanisms that have various time scales: some complete their work in milliseconds, while others span durations of seconds or minutes. It is likely that the great variety of cell types, neurotransmitters, and receptors is designed to accommodate this wide range of timescales.

It is important to point out here that adaptation to (spatial) contrast is different from light adaptation because it is pattern specific: adaptation to a stimulus of some orientation and spatial frequency will have little or no effect on the sensitivity to stimuli of different spatial characteristics (Movshon, J. A. and Lennie, P., 1979). This is especially apparent in the cortex, but has been demonstrated in the retina as well (Hosoya, T. *et al.*, 2005).

2.03.3.5.2 Retina

Early work has identified a retinal mechanism of adaptation to contrast, dubbed the Contrast Gain Control, which acts rapidly to adjust the (temporal) contrast sensitivity of RGCs, and to produce a phase shift in the response as contrast increases (Shapley, R. M. and Victor, J. D., 1978; Benardete, E. A. *et al.*, 1991). The spatial and dynamical properties of this mechanism suggest that it is mediated by an extensive network of amacrine cells. More recent work found two processes of retinal adaptation to contrast: fast (<0.1 s) and slow (~10 s; Chander, D. and Chichilnisky, E. J., 2001; Baccus, S. A. and Meister, M., 2002). The cellular basis of these processes remains to be established.

2.03.3.5.3 Lateral geniculate nucleus

The effects of contrast and luminance on LGN cells is roughly similar to their effects on RGCs. Recently, vision scientists have been paying more attention to the visual content of natural scenes, because it was thought, reasonably, that the visual system might

have evolved specialized mechanisms to deal with the visual world. Mante V. *et al.* (2005) have found that luminance and contrast vary independently in natural scenes, and that the actions of the adapting mechanisms (gain control) for luminance and for contrast are also independent, at least as they are expressed in the responses of LGN cells. It remains to be determined whether the same independence holds for subsequent stages in the visual system.

2.03.3.5.4 Visual cortex

Ohzawa I. *et al.* (1982; 1985) investigated the effect of ambient contrast on the response versus contrast function of cortical neurons. They found a contrast gain control mechanism that differs from the retinal one in several ways: it is slower (with a time constant of ~6 s, compared with a few milliseconds for the retinal mechanism), and appears to involve only the central discharge zone, while the retinal mechanism extends over a wide region. This mechanism is quite effective: contrasts as low as 3% can double the contrast threshold.

2.03.3.5.4.(i) Monocular versus binocular Anzai A. *et al.* (1995) found that contrast thresholds and slopes varied from cell to cell but, in general, binocular contrast thresholds were lower, and binocular slopes were steeper, than their monocular counterparts. Truchard A. M. *et al.* (2000) demonstrated that contrast gain reductions are made primarily at a monocular site, before the convergence of information from the two eyes takes place.

2.03.3.5.4.(ii) Contrast gain or response gain? We note that not only aspects of the stimulus can affect the sensitivity to contrast, but also the internal state of the observer. For example, attention can affect the response of cortical neurons to contrast, and such a modulation could reflect either a change in the effectiveness of the stimulus (changed effective contrast) or a different response amplitude due to a scaling effect of attention. In a recent study, the behavior of most neurons in V4 favored the hypothesis that attention increased significantly the effective contrast (Reynolds, J. H. *et al.*, 2000; Reynolds, J. H. and Chelazzi, L., 2004). Qualitatively similar results were obtained in neurons from the middle temporal (MT) area of primate by Cook E. P. and Maunsell J. H. R. (2004). For a discussion of the ways in which attention modulates neuronal responses in the visual cortex see Maunsell J. H. R. and Treue S. (2006).

2.03.3.5.5 Cellular basis of contrast adaptation in cortex

As in the retina, contrast is calculated across an extended region of cortex, and the result is used by the cortical contrast adaptation mechanisms to adjust the contrast gain of cortical units. The prevailing view is that this is accomplished by division, probably by shunting inhibition (Carandini, M. and Heeger, D. J., 1994; Carandini, M. and Ferster, D., 1997; Cavanaugh, J. R. *et al.*, 2002), but other mechanisms have been suggested, such as synaptic depression, either of intracortical synapses, or of the thalamocortical synapse (Carandini, M. *et al.*, 2002). Synaptic depression can exert a powerful influence on cortical dynamics (Chance, F. S. *et al.*, 1998), but there is still some doubt about its functional importance, because in recordings *in vivo* it is considerably less powerful than it appears in cortical slices (Sanchez-Vives, M. V. *et al.*, 2000). This topic is still being investigated by several groups, and it is likely that more than one mechanism will eventually be implicated.

It has been shown that the effect of contrast adaptation is to produce a sustained hyperpolarization in cortical neurons (Carandini, M. and Ferster, D., 1997; 2000; Sanchez-Vives, M. V. *et al.*, 2000), which reduces their firing rate without a significant change in their conductance.

A recent study, which used natural stimuli to explore how the stimulus ensemble shapes the receptive field properties of cortical neurons, found that contrast adaptation can be very slow (tens of seconds or more), and that it optimizes the spatiotemporal properties of the receptive field to maximize information transmission in the visual cortex (Sharpee, T. O. *et al.*, 2006). It appears, therefore, that several mechanisms, each with its own timescale, are marshaled in the service of this important adaptation process.

2.03.3.5.6 Contrast adaptation in parallel visual streams

In agreement with previous results (Benardete, E. A. *et al.*, 1992), Solomon S. G. *et al.* (2004) reported that contrast adaptation is profound in the magnocellular stream (beginning already in RGCs), but absent in the parvocellular or koniocellular stream. One interpretation of these results is that contrast adaptation requires summation of many inputs, and it is thus the larger receptive fields of the M stream (Gouras, P., 1968; Croner, L. J. and Kaplan, E., 1995) that endow them with greater ability to adapt to the ambient contrast. This difference between the various neuronal populations could be a quantitative rather than a

qualitative one: the tiny receptive field centers of the midget (P) ganglion cells allow little or no amacrine input, while the much larger centers of parasol (M) neurons can benefit from numerous such inputs.

2.03.3.6 Adaptation and Absolute Levels of Contrast and Luminance

Adaptation to luminance or contrast sacrifices the information about the absolute levels of these quantities. This is, again, a general theme in the nervous system: emphasize the change at the expense of the unchanging. We note, however, that some elements in the nervous system do seem to keep track of the absolute levels, and are thus immune to adaptation. Examples include the melanopsin-containing RGCs (Berson, D., 2003) and those cortical units that show no sign of contrast adaptation (Ohzawa, I. *et al.*, 1985).

2.03.3.7 Effects of Luminance Level on Contrast Sensitivity

Shakespeare already knew that a bright light makes a faint one more difficult to see, as Nerissa says in The Merchant of Venice "When the moon shone, we did not see the candle" (act 5, scene 1). In the nineteenth century, Weber determined experimentally that, at low and moderate intensities, the change in perceptual intensity is roughly proportional to the change in the stimulus: $dp = k \cdot dI/I$ (Weber's law, which is sometimes written simply as $dI/I = k$). At high intensities a saturation or compression sets in, and renders Weber's law invalid for these intensities.

If we integrate Weber's law we get Fechner's law: $p = k \cdot \log(I) + c$, which shows the well-known logarithmic compression of physical intensities when they are represented by the nervous system. In assuming a linear response at low intensities, the Weber–Fechner relationship does not account for the initial expanding nonlinearity that is often seen in visual neurons. This expansive nonlinearity has been proposed as one of the mechanisms that are used in the cortex to sharpen the tuning of cortical neurons (Albrecht, D. G. and Geisler, W. S., 1994), since it causes small responses to be amplified less than larger ones.

We note that the effect of ambient luminance on contrast sensitivity, as manifested in Weber's law, is a clear demonstration of adaptation at work.

2.03.4 Psychophysical Aspects

2.03.4.1 Steady State

2.03.4.1.1 Luminance

Can we tell how bright the world really is? Psychophysical experiments in humans, in which the stimuli provided no spatial cues (Gantzfeld), found that the sensation of brightness is graded over approximately 8 log units (Barlow, R. B. and Verrillo, R. T., 1976), suggesting that somewhere in the visual system there are neurons that encode luminance over several log units. This wide range is noteworthy, because each class of vertebrate photoreceptors (rods or cones) can vary its response to light over only ~4 log units (Fain, G. L. and Dowling, J. E., 1973; Dacey, D. M. *et al.*, 2005), although some invertebrate photoreceptors can encode light intensity over 10 log units (Kaplan, E. and Barlow, R. B., 1975). Thus it is likely that low luminance is encoded by rods, and higher luminance sensitivity results from the activity of cones and of the few specialized ganglion cells that contain melanopsin (Berson, D., 2003).

Perceptual brightness increases with luminance according to a power law: $B = k \times Lp$, where B is subjective brightness, L is luminance, and k and p are constants (Stevens, S. S., 1970). The exponent p has been found to be nearly one-third for brightness. Stevens has argued that the power law, which holds for all sensory modalities (each with its own distinctive exponent), is a more complete and faithful description of the relationship between perceptual magnitude and physical intensity than Fechner's much older logarithmic law (Stevens, S. S., 1961).

2.03.4.1.2 Contrast

Figure 2, in which contrast increases from top to bottom on the ordinate and spatial frequency increases from left to right on the abscissa, shows that we are most sensitive to intermediate spatial frequencies, with sensitivity to higher and lower frequency being much lower (Limitations of the printing process create distortion of the shape of the filter at high spatial frequencies in Figure 2). This forms a spatial band-pass filter, which is often called the contrast sensitivity function, and to the extent that we can think of the visual system in linear terms, we can imagine it to represent the envelope of many, much narrower, spatial filters, each with a peak at a slightly different spatial frequency, similar to the

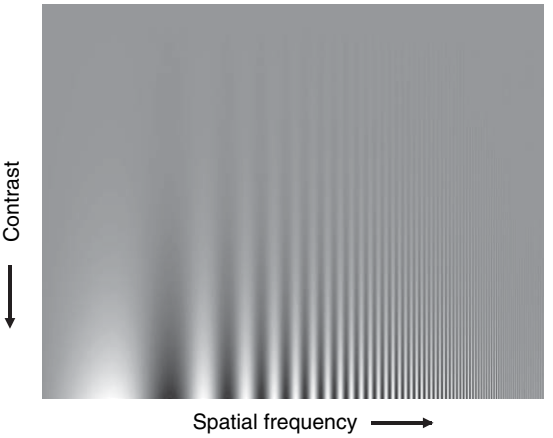

Figure 2 The (spatial) contrast sensitivity function. Contrast increases from top to bottom, and spatial frequency increases from left to right. From the appropriate distance, you can see that intermediate spatial frequencies can be seen at lower contrasts than either higher or lower spatial frequencies, creating an inverted U shaped function (for more information about this figure, which was created by J. Robson and F. Campbell, see: http://ohzawa-lab.bpe.es.osaka-u.ac.jp/ohzawa-lab/izumi/CSF/A_JG_RobsonCSFchart.html).

filter shown in Figure 1 (Campbell, F. W. and Robson, J. G., 1968). This is the origin of the notion, which was rather popular in the past, that the visual system might perform something akin to Fourier analysis on the visual world (e.g., Pollen, D. A. *et al.*, 1971; De Valois, K. K. *et al.*, 1979; Pollen, D. A. and Ronner, S. F., 1981). This idea, which relies entirely on linear mechanisms and interactions, had been criticized on theoretical grounds (e.g., Schwartz, E. L., 1980), and was mortally wounded by the discovery (Enroth-Cugell, C. and Robson, J. G., 1966) that the mammalian visual system includes a class of nonlinear neurons. That discovery, however, ushered in a new view of sensory information processing, which holds that information is processed by parallel neuronal populations, such as the M, P, and K streams, or the what and where streams (for a review, see Chapter The P, M and K Streams of the Primate Visual System: What Do They Do for Vision?), and by other considerations (e.g., Schwartz, E. L., 1980). In general, most visual neurons show some spatial tuning, which results from the antagonistic interplay of excitatory and inhibitory processes of quite different spatial scales (see Figure 1). The sharpness of this tuning increases as one moves from RGCs to LGN and primary visual cortex, at least for some classes of neurons.

2.03.4.1.3 Mach bands and other illusions

The notion that a spatial comparison of two antagonistic inputs of different scales will lead to tuning, and thus to an emphasis on intermediate and high frequencies at the expense of low ones, was already appreciated by E. Mach in the 1860s, when he realized that this could explain the enhancement of edges at light–dark borders (Mach Bands: Ratliff, F., 1965). In fact, Mach attempted to determine, from the width of the bright and dark bands, the extent of the retinal inhibitory influences that he surmised were responsible for that illusion. Neurophysiological experiments, carried out more than a century later, have confirmed his remarkable intuition (Enroth-Cugell, C. and Robson, J. G., 1966; Barlow, R. B. and Quarles, D. A., 1975).

A related illusion is the Craik-Obrien-Cornsweet illusion (for a demonstration, see Relevant Website Section), which is due, again, to the fact that we respond better to abrupt changes than to gradual ones.

2.03.4.2 Dynamics

We have seen that the visual system is more sensitive to change than to unchanging conditions. This is true not only in space but also in time: flicker is more visible than steady light. The human sensitivity to flicker at various frequencies, and its dependence on the ambient illumination (and on other stimulus parameters), has been the subject of intensive investigation since the 1950s (De Lange, H., 1958a; 1958b). The influence of the luminance level on the temporal contrast sensitivity function can be clearly seen in Figure 3: at low luminance levels the function is that of a low-pass filter. As luminance level increases, a band-pass filter emerges, rather similar to what we saw in the spatial domain (Figure 2). Both flicker sensitivity and the maximal flicker frequency that can be resolved (the critical fusion frequency) increase with luminance level.

2.03.4.2.1 Cellular basis of the temporal contrast sensitivity function

The function shown in Figure 3 reflects primarily the basic properties of photoreceptors, although several stimulus parameters (such as target size or retinal eccentricity) do influence the details of this important psychophysical function. The cellular basis that underlies it has been discovered in the primordial photoreceptors of the horseshoe crab, *Limulus* (Dodge, F. A. *et al.*, 1968) (*Limulus* is thought to be the oldest living creature on our planet, and fossils

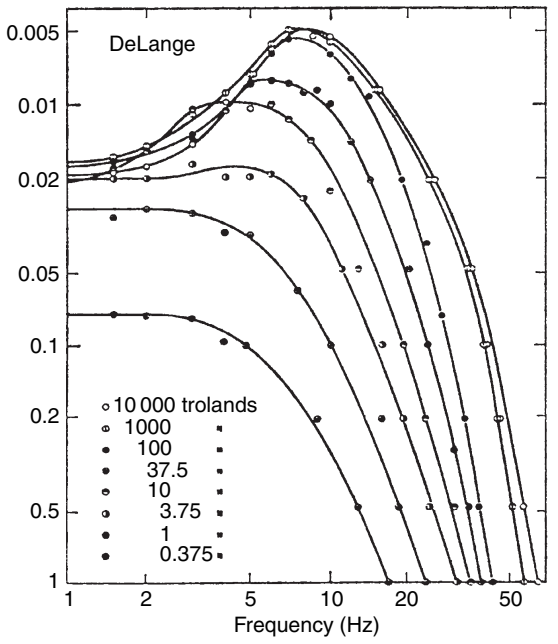

Figure 3 The human contrast sensitivity as a function of temporal frequency at several luminance levels. The axes are logarithmic. Contrast sensitivity and critical fusion frequency both increase with luminance level. Retinal illumination is given in trolands (luminance times the pupil area). Reproduced from De Lange, H. 1958a. Research into the dynamic nature of the human fovea–cortex systems with intermittent and modulated light. I. Attenuation characteristics with white and colored light. J. Opt. Soc. Am. 48, 777–784, with permission from the Optical Society of America.

with eyes remarkably like those of modern-day horseshoe crabs date back at least 300 million years). That study has demonstrated that light adaptation reduces the amplitude and duration of the quantal bumps, which are discreet responses to individual photons, and which sum up to produce the receptor's response to light. The major features of the De Lange celebrated function (the increased flicker sensitivity, the change from a low-pass to a band-pass behavior, and the decreased duration of temporal integration) have all been replicated in the individual photoreceptor, providing an impressive, and rare, link between biophysical processes and perceptual experience.

We can also relate the behavioral change in sensitivity depicted in Figure 3 to the contrast gain of visual neurons. As mentioned above, over a wide range of luminance, from scotopic levels up to high mesopic levels, as luminance increases, so does the contrast gain (Purpura, K. *et al.*, 1988).

2.03.4.3 Stimulus Parameters

As we have seen, contrast and luminance sensitivities are central to the process of vision. It is not surprising, therefore, that they are affected by most other aspects of the visual stimulus, such as size, retinal eccentricity, color, state of light or dark adaptation, and so on. A review of all these is outside the scope of this chapter, but comprehensive summaries of the early literature can be found in reviews by Blackwell H. R. (1972) and by Kelly D. H. (1972) and in the studies of Koenderink J. J. *et al.* (1978a; 1978b; 1978c; 1978d).

2.03.4.4 Some Clinical Implications

The growing appreciation of the importance of contrast sensitivity for vision has added new tests to the eye clinic, where letter charts (Pelli, D. G. *et al.*, 1988) and other devices are being used to supplement the venerable Snellen eye chart. The Snellen chart measures only acuity, the ability to see the highest spatial frequencies, but provides little information about the rest of the contrast sensitivity function (Figure 2). However, adequate contrast sensitivity across medium and low-spatial frequencies is essential for many visual tasks (Lennerstrand, G. and Ahlström, C. O., 1989).

Under certain pathological conditions, contrast sensitivity is compromised, and because of the crucial role that it plays in vision, such deterioration has serious consequences for the affected person. With age, a deterioration of the eye's optics (increased lens opacity, cataracts) increases glare which reduces the image contrast that is available to the retina. Aging thus causes a decrease in contrast sensitivity and an increase in the time to recover from glare, due to both optical and neural factors (Sloane, M. E. *et al.*, 1988; Sturr, J. F. *et al.*, 1988; Skeel, R. L. *et al.*, 2006), although under photopic conditions the optical factors appear to be dominant (Burton, K. B. *et al.*, 1993). In age related macular degeneration and drusen, contrast sensitivity is decreased at the peak and at the high-frequency end of the contrast sensitivity function (Kleiner, R. C. *et al.*, 1988). Other pathologies that affect contrast sensitivity at various spatial frequencies include retinitis pigmentosa (Alexander, K. R. *et al.*, 2004), dyslexia (Bednarek, D. B. and Grabowska, A., 2002, although this is highly controversial), amblyolpia (Bradley, A. and Freeman, R. D., 1981; Chino, Y. M. *et al.*, 1991; Asper, L. *et al.*, 2000), and glaucoma (Swindale, N. V. *et al.*, 1996; Raz, D.

et al., 2002; Altangerel, U. *et al.*, 2006). The cause of contrast sensitivity reduction in all of these is neural, rather than optical.

2.03.4.5 From Neurons to Perception

It is tempting to relate the results of neurophysiological experiments (usually done on anesthetized animals) to perception and psychophysics (usually studied in conscious humans). This is one of the major goals of neuroscience, and several partially successful attempts have been made (e.g., see Ratliff, F., 1965; Geisler, W. S., 1989), but its accomplishment is hampered by severe limitations, which include the following: (1) much of the analysis treats neurons and interactions as linear, while they are manifestly nonlinear (most response vs. contrast functions show nonlinearities, and the contrast gain control, especially in the cortex, is a nonlinear mechanism); (2) our knowledge of the wiring, biophysics, and neurochemistry of the brain is still far from complete; and (3) there are technical limitations in physiological experiments, which further restrict our knowledge base. For more on this important subject, see Olshausen B. A. and Field D. J. (2005).

2.03.5 Conclusions

The visual system is exquisitely sensitive to both spatial and temporal contrast, which it extracts from the visual scene by comparing the luminance at several points in space and time. It derives this sensitivity primarily from the antagonistic interplay of two processes that have two very different scales: one fine (fast) and the other coarse (slow). The system pays much less (direct) attention to luminance, although the luminance level does affect strongly the sensitivity to contrast. The brain has evolved an elaborate set of adaptive mechanisms, active at several stages along the path from retina to cortex, which adjust the sensitivity to contrast depending on both the ambient contrast and prevailing luminance. Thus luminance, contrast and adaptation all interact to permit the brain to focus on what is important in the visual scene: the new and unexpected.

2.04.4	Neural Mechanisms of Filling-In	49
References		51

The main topic of this chapter is how our visual system processes the visual information related to the sense of brightness or lightness which is one of the most basic visual perception. The psychophysical and physiological findings on this topic will be summarized and recent advances on the understanding on the mechanisms of perceptual filling-in, which is closely related to the brightness/lightness perception, will be described.

At the outset, the difference among three related words should be clarified, namely, luminance, brightness, and lightness. All three are psychophysical measures of light intensity and are distinguished from physical measures such as light energy or number of quanta of light. Of the three, luminance is an objective measure of light intensity at a certain point in the visual field that can be measured by a device. The latter two, brightness and lightness, are both subjective measures of light intensity. Brightness refers to apparent light intensity of a stimulus in general or, more specifically, that of a light source. Lightness refers to the apparent surface reflectance which ranges between white and black.

2.04.1 Influence of Contrast on Perceived Brightness and Lightness

Perceived brightness of a stimulus depends on the light intensity coming from the stimulus to the eye, namely the luminance of the stimulus. When the luminance increases, the perceived brightness increases; their relationship obeys Stevens' law and can be represented by a power function. However, the perceived brightness of a stimulus patch is influenced by the surrounding stimuli. This is called brightness induction. When two stimuli with different luminance are placed next to each other, the difference in the perceived brightness between the two stimuli is often enhanced. This phenomenon is called brightness contrast. In Figure 1, each circle has the same shade of gray and the same luminance. However, because of the difference in the luminance of the surrounding region of each circle, the brightness of each circle appears different. This is an example of brightness induction. Brightness induction occurs across a considerably wide area in the visual field up to about 10° in visual angle (Yund, E. W. and Armington, J. C., 1975). Brightness induction can be generated by temporally changing surroundings. When the luminance of the surround is temporally modulated sinusoidally while keeping the luminance of the center patch constant, the brightness of the center patch appears temporally modulated in the opposite phase. Temporal characteristics of the brightness induction has been measured by changing the temporal frequency of the modulation of the surround. It was found that brightness induction occurs for the temporal frequency up to 1–4 Hz depending on the spatial frequency of the stimulus, but it did not occur for the faster modulation (De Valois, R. L. *et al.*, 1986; Rossi, A. F. and Paradiso, M. A., 1996). In contrast, we can easily perceive the flicker of the center patch over 10 Hz when the luminance of the patch itself is modulated. This indicates that the brightness induction requires extra processing, which is rather slow compared with the mechanism to detect luminance change at a certain position in the visual field.

There is tendency that lightness stays constant even when illumination changes. This is called lightness constancy. For example, when we read a newspaper, the letters look black and the paper looks white regardless of being under indoor illumination or in sunshine, even though the intensity of illumination is 100–1000 times stronger outdoors and

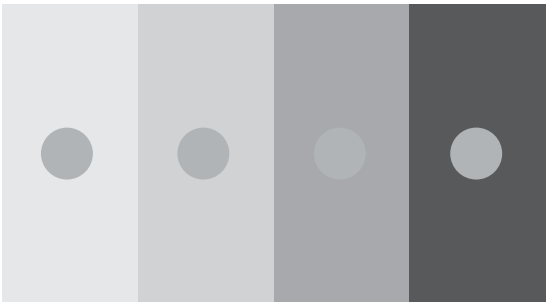

Figure 1 Brightness induction. The four circles have the same shade of gray and have the same luminance. However, because of the difference in the luminance of the background, they look to have different brightness.

the light reflected from the letter is enormously different. Wallach H. (1948) revealed that the luminance ratio between the surface and the surround region is the major factor determining the lightness of the surface. As long as the luminance ratio between the surface and surround is kept constant, the lightness of the surface stays constant even when the illumination changes. One remaining problem is that, according to this theory, only relative lightness can be determined. The visual system must somehow assign absolute value such as white or black to each surface. A simple heuristic mechanism is suggested in which white is assigned to the brightest surface in the scene (Gilchrist, A. *et al*., 1999).

The importance of the luminance ratio between the neighboring regions in lightness perception does not imply that lateral interaction between the neighboring region on the retinal image is the sole factor. Much evidence suggests that more complicated processes are involved. One example is shown in Figure 2, where the gray regions exist within black and white square-wave grating. Although the gray regions to the left and to the right have the same luminance, their brightness appears quite different. When we inspect the boundaries between the gray region and either the black or white stripes, for the gray region to the left, the boundary with the black stripe is longer than that with the white stripe, whereas for the gray region to the right, the opposite is true. If the amount of luminance contrast between the neighboring region is proportional to the boundary length, we can expect that the gray region at the left appears brighter that that at the right. However, contrary to expectations, the gray region at the right appears brighter than that at the left. This is discovered by White M. (1979) and is known as White's effect. One possible reason for such an effect is that

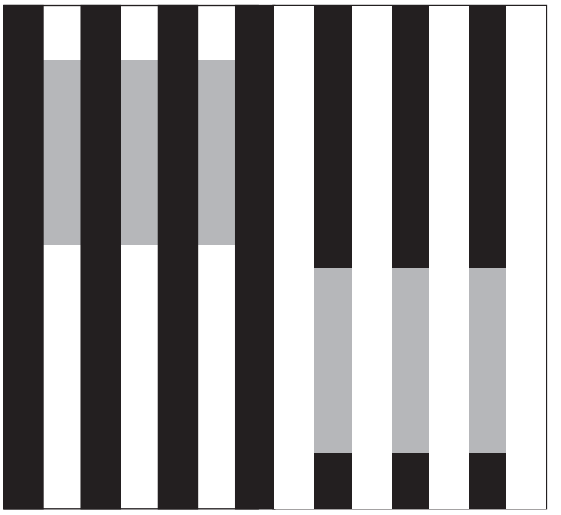

Figure 2 White's effect. Gray rectangles at the top left and bottom right have the same luminance, but appear to have quite different brightness.

when the boundaries between three regions form a T-junction, luminance contrast is mainly computed across the boundary between the regions that share the terminated edge of the T-junction (e.g., white and gray regions to the left; Moulden, B. and Kingdom, F., 1989; Todorovic, D., 1997).

Three-dimensional interpretation of the scene or tranparency also strongly influence on the lightness perception (Gilchrist, A. L., 1977; Adelson, E. H., 1993; Anderson, B. L. and Winawer, J., 2005). Gilchrist A. L. (1977) has shown by using a stimulus configuration shown in Figure 3(a), that luminance contrast is computed between regions on the same depth plane. In his setup, the horizontal plane contained a large white square and a small black trapezoidal tab that extended outward toward the subject. The vertical plane contained a large black square and a small white tab that extended upward. When the subject looked at the scene through a small hole, the scene looked like the one shown in Figure 3(b), and the right tab appeared to be on the same plane as the large white surface, and the left tab appeared to be on the same plane as the large black surface. In this situation, the right tab looked black, and the left tab looked white. In contrast, when the subject saw the scene binocularly, the three-dimensional structure of the scene was correctly perceived, and the right tab looked white and the left tab looked black. This result indicates that surface lightness perception is not determined by the surface luminance or the contrast on the retinal image, instead, it

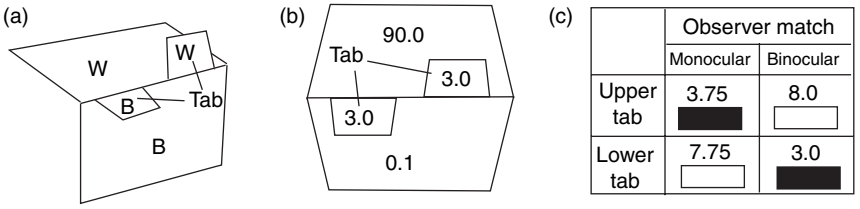

Figure 3 An experiment by Gilchrist A. L. (1977) that showed the three-dimensional perception of the scene strongly influences lightness perception. (a) Configuration of the stimulus used (B, black; W, white). (b) Monocular image of the scene with luminance of each region in foot-lamberts. (c) Average match of two tabs with Munsell swatch in monocular and binocular conditions. Adapted from Gilchrist, A. 1977. Perceived lightness depends on perceived spatial arrangement. Science 195, 185–187.

is determined after or at least in parallel with the analysis of depth structure of the scene or segmentation/grouping of the scene.

2.04.2 Neural Mechanisms of Brightness/Lightness Perception

Retinal ganglion cells and neurons in the lateral geniculate nucleus (LGN) have receptive fields with concentric center-surround organization. As a result of imbalance between the center and surround, these neurons can transmit luminance signals at low spatial frequency to the primary visual cortex (V1). These neurons include ON-type that increase the activity when the light intensity increases and OFF-type that decrease the activity. In V1, many neurons have orientation selectivity and respond well to the contrast at the border of the surface region, and they encode the magnitude of the contrast and some of them also encode the polarity of the contrast. A minority of V1 neurons respond to a uniform surface that covers the receptive field (surface-responsive neuron) and can transmit the information of the luminance of the surface. Thus, if we consider the population activity of V1 neurons, when we see a uniform surface, strong activity occurs at the position corresponding to the edge of the surface, and weak activity extends across the region corresponding to the interior of the surface (Friedman, H. S. *et al.*, 2003).

With regard to lightness perception, the properties of surface-responsive neurons are of particular interest because these neurons must carry signals concerning the visual attributes of the surface. Surface-responsive neurons include cells whose activity increases monotonically with either the increase or decrease of the surface luminance (Kayama, Y. *et al.*, 1979; Kinoshita, M. and Komatsu, H., 2001). Figure 4(a) shows an example of a surface-responsive V1 neuron that showed response increase with an increase in the surface luminance. It is also reported recently that some of surface-responsive neurons maximally responded at intermediate luminance (Peng, X. and Van Essen, D. C., 2005).

As was described in the previous section, perceived brightness/lightness of a surface region depends on the luminance contrast with the surrounding region. It has been shown that the responses of many surface-responsive neurons are modulated by changing the luminance of the surrounding region. Figure 4(b) shows the responses of the same neuron as in Figure 4(a) when the luminance of the surrounding annulus was changed while the luminance of the surface covering the receptive field was kept constant. Although the surrounding annulus is sufficiently away from the receptive field, the response of this neuron changed depending on the luminance of the annulus. The response change occurred in the direction consistent with the brightness induction. That is, this neuron increased activity with the luminance of the surface covering the receptive field increased (Figure 4(a)), and when the luminance of the surrounding annulus decreased (Figure 4(b)). In both cases, the perceived surface brightness on the receptive field increased. About two-thirds of the surface-responsive neurons studied by Kinoshita M. and Komatsu H. (2001) were influenced by the luminance of the surrounding annulus away from the receptive field, and about half of these showed responses that can qualitatively account for the brightness induction.

Paradiso and colleagues have shown that V1 neurons in cats exhibit response change when the luminance of the surround was temporally modulated while the luminance of the surface covering the receptive field was kept constant (Rossi, A. F. *et al.*, 1996; Rossi, A. F. and Paradiso, M. A., 1999). The same neurons also responded when the

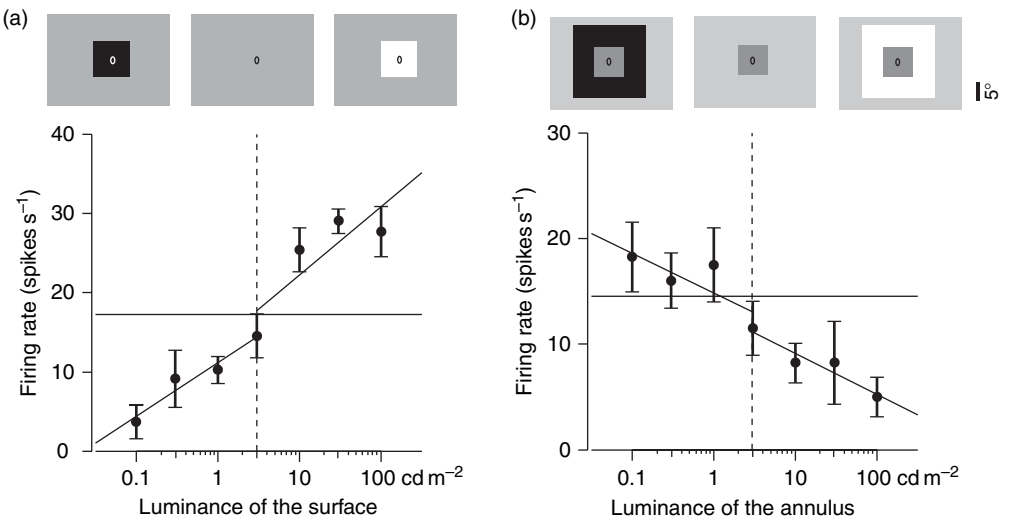

Figure 4 Responses of a surface-responsive V1 neuron when the luminance of the surface covering the receptive field (a) or the annulus apart from the receptive field (b) was changed. Schematic illustration of the stimulus is shown at the top, and a small oval is the receptive field. Adapted from Kinoshita, M. and Komatsu, H. 2001. Neural representation of the luminance and brightness of a uniform surface in the macaque primary visual cortex. J. Neurophysiol. 86, 2559–2570, used with permission.

luminance of the surface covering the receptive field was temporally modulated. In many neurons, the response change in these two conditions occurred in the opposite phase, but in both cases, it corresponded to the temporal change in the perceived brightness of the surface covering the receptive field. Even more interestingly, when the temporal frequency of the luminance change was increased, the response peaked at about 1 Hz and then decreased for the faster modulation of the surround luminance, whereas the responses still increased when the luminance of the surface covering the receptive field was modulated in higher temporal frequency. This is consistent with the lower cut-off in the brightness induction observed in psychophysical experiments (De Valois, R. L. *et al.*, 1986; Rossi, A. F. and Paradiso, M. A., 1996). These results indicate that response properties of some V1 neurons closely correlate with brightness induction. The same authors also conducted a similar test in LGN and the optic tract fibers, and found that only a few LGN neurons and no optic tract fibers correlated with the perceived brightness (Rossi, A. F. and Paradiso, M. A., 1999). This indicates that V1 is the first place where lateral interaction necessary for brightness induction takes place. In contrast, as is described in the previous section, various factors more complicated than the computation of luminance ratio between the neighboring regions is involved in the lightness perception, and neural processes related to such higher order computation have not been studied yet. In recent years, many studies have shown that responses of early visual areas such as V1 and V2 are influenced by higher order structure of the image such as the figure-ground organization or the three-dimensional structure of the scene (Zipser, K. *et al.*, 1996; Sugita, Y., 1999; Bakin, J. S. *et al.*, 2000; Zhou, H. *et al.*, 2000). We can conceive that this higher order information is combined with the simpler luminance and contrast information, and activities that can account for the complex properties of brightness/lightness perception are generated.

2.04.3 Perceptual Filling-In

As described above, perceived brightness of a region in the visual field is strongly influenced by the contrast at the edge of the region. It is important to realize that contrast information does not localize at the edge, instead it spreads across the entire region and influences the perceived brightness of the region. This fact can be clearly demonstrated by the Craik–O'Brien–Cornsweet illusion (Cornsweet, T., 1970) as shown in Figure 5. The luminance profile across this figure is shown at the bottom. It contains a sharp luminance change at two edges, one at the left one-third and the other at the right one-third of the figure where a large

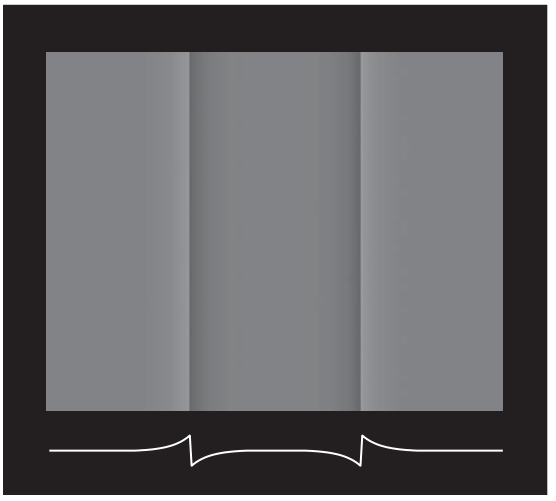

Figure 5 Craik–O'Brien–Cornsweet illusion. The luminance profile is shown below. There appears a wide dark band at the middle part although the luminances at the center & both right and left ends are the same.

contrast signal is generated in the cortex. At both sides of either edge, the luminance change is more gradual and the resulting contrast signal should be much weaker. The luminance at both ends of this figure is the same as that at the center of the figure, but the center looks much darker than the ends. This is because the contrast signal detected at the edges spreads across the regions at either side of the edges, and affects the perceived brightness of the regions.

Perceptual phenomenon like this is called filling-in, in which visual features, such as color, brightness, texture, and motion of the surrounding area are perceived in a certain part of the visual field even though these features are not physically present. The Craik–O'Brien–Cornsweet illusion demonstrates that at least two separate processes, one a contrast detection, the other a filling-in, operates as the underlying mechanisms for brightness perception to occur. In an ordinary situation in which visual stimulus physically exists, in addition to these two sorts of information, luminance information generated by the stimulus itself must be also taken into account as described in the previous section.

Perceptual filling-in is observed in various situations (Pessoa, L. *et al.*, 1998; Komatsu, H., 2006). One situation is when some regions of the visual field lack visual inputs because of an innate structure of the retina (blind spot) or circumscribed damage to some part of the retina or the visual system (scotoma). Even though there are no visual inputs within these regions in the visual field, we perceive as if the same visual features as the surrounding visual field exist within these regions. The second situation is when the contrast signal at the edge of an object is reduced as a result of steady fixation (Troxler effect) or stabilization of the retinal image. When this happens, the part of the visual field originally occupied by the object is filled-in with the visual features of the surround. Filling-in also occurs in certain figures without a need of prolonged fixation. One example of such illusion is the neon color spreading in which faint color spreads across a region enclosed by an illusory figures. Another example of filling-in that occurs without prolonged fixation is the Craik–O'Brien–Cornsweet illusion.

Filling-in should be considered as an essential part of normal surface perception rather than a special phenomenon. Paradiso M. A. and Nakayama K. (1991) demonstrated this by examining the spatiotemporal properties of masking of brightness perception. In their experiments, a large uniform disk was followed by a small mask such as a ring after a short interval of time (50–100 ms of stimulus-onset asynchorony). Suppression of the brightness occurred inside the mask where the brightness of the disk was blocked and that of the background was perceived. The latest time at which masking was effective was correlated with the distance between the edge of the disk stimulus and the contour of the mask. These results suggest that some process of filling-in occurs even when we see a uniform surface in the normal visual field.

Because filling-in requires lateral spread of visual information across a wide area in the visual field, horizontal connections in the visual cortex or feedback connection from higher areas to lower areas are thought to be responsible for filling-in. It should be noted, however, that filling-in includes processes more complicated than simple lateral spread of visual information. For example, Nakayama, K. *et al.*, (1990) have shown that neon-color spreading is strongly influenced by three-dimensional structure of the scene. Therefore, it may not be surprising that brightness/lightness perception is influenced by a higher order structure of the image if we consider that filling-in is critically involved in the underlying processes for brightness/lightness perception.

2.04.4 Neural Mechanisms of Filling-In

Mechanisms of filling-in are not well understood. Different types of filling-in may have different

underlying mechanisms. One extreme possibility is that visual system simply ignores the lack of information at a certain region in the visual field, and filling-in is a passive outcome of this. However, various observations suggest that some active processes are involved in the occurrence of filling-in. For example, it has been shown that removal of a stimulus that induced filling-in evokes an afterimage or aftereffect of the filled-in attributes (Ramachandran, V. S. and Gregory, R. L., 1991; Murakami, I., 1995). Without some active process, it is hard to understand why these events happen.

In recent years, attempts to study neural mechanisms of filling-in have been made, and neuron recordings from monkey visual cortex and functional magnetic resonance imaging (fMRI) experiments in human visual cortex were conducted. These experiments have employed a common strategy: they examined whether neurons are activated in the region of the retinotopic map of early visual areas that represented the interior of the surface where filling-in occurred. As described in the previous section, it is very likely that filling-in commonly occurs when we see an ordinary visual object in everyday life. However, in such an ordinary situation, it is hard to dissociate neuron activities evoked by the visual features present within the contour of object and those evoked by the lateral spread of contrast detected at the contour. In contrast, for the case of filling-in phenomena, neuron activities due to the lateral spread can be isolated because no visual features exist within the region under investigation. This strategy is conceptually the same as the one used to study neural representation of illusory contour; it has been shown that neurons in area V2 of monkey visual cortex are activated when illusory contour is perceived across the receptive field even though no contour is physically present (von der Heydt, R. *et al.*, 1984).

Several studies have been conducted to record neuronal activities related to filling-in at the blind spot (Fiorani, M. *et al.*, 1992; Komatsu, H. *et al.*, 2000; Matsumoto, M. and Komatsu, H., 2005). In monocular viewing, if the blind spot of the opened eye is covered by a surface with uniform color and brightness, the same color and brightness is perceived to fill in the blind spot even though there is no visual input in the blind spot (filling-in at the blind spot). Likewise, if a bar stimulus is presented across the blind spot, a complete bar is perceived (completion). It has been shown that, in these situations, some neurons located at the deep layer of V1 region that represented the visual field corresponding to the blind spot are activated. Response properties of these neurons are shown to be consistent with the characteristics of filling-in and completion at the blind spot. As there is no retinal input to this region in V1, neuron activities observed in these studies must be generated as a result of the lateral spread from the surrounding region. Neural responses related to the Craik–O'Brien–Cornsweet illusion were recorded by Roe A. W. and colleagues (2005). They examined neuron activities from the region corresponding to the visual field where brightness was induced, and found that neurons in the thin stripe of area V2 are activated. Neural responses related to the filling-in of dynamic texture stimulus within an empty region were examined by De Weerd, P. *et al.* (1995). They found that neurons in areas V2/V3 of monkeys having receptive fields in the empty region gradually increased activities with a time course similar to the occurrence of filling-in by the same stimulus in human subjects. These experiments show the possibility that lateral spread of neuron activities across the early visual areas such as V1, V2, or V3 are involved in the occurrence of these filling-in phenomena. In contrast, von der Heydt R. *et al.* (2003) failed to find neuron activities associated with the occurrence of filling-in of the Troxler effect in either V1 or V2.

Two different ideas about the neural mechanisms of filling-in have been proposed (Pessoa, L. *et al.*, 1998; Komatsu, H., 2006). One is the symbolic (or cognitive) theory. According to this theory, only the contrast information at the object contour is detected in the early visual area, and in the higher area, when object image is reconstructed based on this information, color and brightness at the interior of object are assigned. Another theory is the isomorphic theory. This theory assumes that two-dimensional array of feature sensitive neurons are activated in the early visual area are as a result of lateral spread of contrast signals detected at the border, and color and brightness at the interior of the object are represented by the activities of these neurons. The experiments described above suggest that, for some filling-in phenomena such as the Craik–O'Brien–Cornsweet illusion and texture filling-in, neuron activities occur in the visual areas as early as V2 in a manner consistent with the isomorphic theory. In contrast, the results of neural recordings about the Troxler effect is more consistent with the symbolic theory. With regard to the filling-in at the blind spot, the results appears not entirely consistent with either of

the above two theories because neural activation in V1 was observed mainly in deep layers. As an alternative possibility, Komatsu H. (2006) suggested that selective activation of neurons in deep layers of V1 that represent a particular spatial scale and that are sensitive to particular features may be important for filling-in at the blind spot.

Human fMRI experiments have also been conducted recently to study neuron activities related to filling-in. Studies examining filling-in at the blind spot (Tong, F. and Engel, S. A., 2001), neon-color spreading (Sasaki, Y. and Watanabe, T., 2004), and visual phantom illusion (Meng, M. *et al*., 2005) found activities related to filling-in in V1 region corresponding to the visual filed where filling-in occurred. In contrast, a study examining the Craik–O'Brien–Cornsweet illusion (Perna, A. *et al*., 2005) has observed activation only in higher visual areas.

Evidence is still too premature to identify precise neural mechanisms of filling-in, but observation of neural activities related to filling-in in early visual areas suggest that it is promising to study the functioning of neural networks in the early visual areas. At the same time, it should be noted that higher-order information strongly influences the filling-in, and neural interactions between higher and lower areas must be an important question to be pursued.

2.05.1 Introduction

For day-active (or diurnal) animals, like ourselves, the visual sense is of paramount importance for orientation, food gathering, and the pursuit of suitable mates. This is hardly surprising since vision during the day is at its most reliable: the abundance of light enables diurnal visual systems to accurately code light intensity contrasts, the nuances of color, and, for those animals that can see it, the plane of polarized light. These reliable signals, in turn, allow diurnal animals a rich visual experience of their habitat and their daily life within it. But what of the multitude of animal species that have most or all of their activity confined to dim light, either in the vast darkness of the deep sea or under the mantle of night? What role, if any, does vision play for these animals?

From the outset, it is important to point out that the nocturnal visual world is essentially identical to the diurnal visual world. The contrasts of objects are identical and so (or nearly so) are their colors (Figure 1). The only distinguishing difference is the mean level of light intensity, which can be up to 11 orders of magnitude dimmer at night. It is this difference that severely limits the ability of imaging devices, such as eyes, to distinguish the colors and contrasts of the nocturnal world. Indeed, many animals, especially diurnal animals, distinguish very little at all. This is because vision in dim light is inherently unreliable. Why is this so? The basic answer is that visual signals in dim light are contaminated by visual noise. Part of this noise arises from the stochastic nature of photon arrival and absorption: each sample of absorbed photons (or signal) has a certain degree of uncertainty (or noise) associated with it. The relative magnitude of this uncertainty is greater at lower rates of photon absorption, and these quantum fluctuations set an upper limit to the visual signal-to-noise ratio (SNR) (Rose, A., 1942; De Vries, H., 1943). As light levels fall, the fewer the number of photons that are absorbed, the greater the noise relative to the

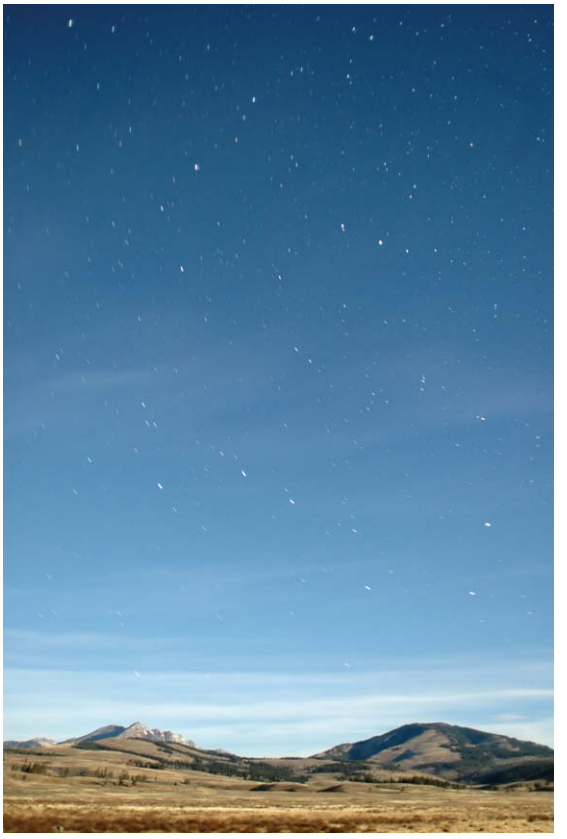

Figure 1 A nocturnal scene photographed with a long (148 s) exposure. This image was taken 3 h after sunset (20.34) on 18 October, 2005, in the northwestern part of Yellowstone National Park, looking north toward the Gallatin Mountain Range that lies between the Park and Bozeman, Montana. An almost full moon had recently risen on the eastern horizon. The scene appears as it would during the day (with the exception of the stars), because Rayleigh-scattered moonlight creates a blue sky and a similar illumination spectrum to sunlight (see Figure 3), only weaker (which the long camera exposure time integrates into a day-like image). Camera details: Nikon D70 digital SLR, Nikkor 20-mm lens, *f*/2.8, ISO 400. The image was very kindly supplied by Dr. Joseph A. Shaw of Montana State University and also appeared as part of a journal cover (Johnsen, S. *et al*., 2006).

signal and the less that can be seen. Signal reliability in dim light can thus be improved with an eye design of higher sensitivity to light.

It is now becoming apparent that the eyes of many nocturnal animals are indeed sufficiently sensitive to permit reliable vision in very dim light. Some animals even have sufficient visual sensitivity to distinguish colors, to detect faint movements, to learn visual landmarks, to orient to the faint polarization pattern produced by the moon, and to navigate using the constellations of stars in the sky. In this review, these impressive visual abilities, and the optical and neural strategies that animals have evolved to improve visual sensitivity, will be explored. Whereas other recent accounts have discussed nocturnal and deep-sea vision in general terms (Warrant, E. J. 2004; Warrant, E. J. and Locket, N. A., 2004; Warrant, E. J. 2006), here, for the sake of brevity, we concentrate on nocturnal vision and nocturnal visual behavior in two model animal groups, one vertebrate and one invertebrate: the birds and the arthropods. Even though most of our recent knowledge about nocturnal vision has been derived from these two groups, reference will also be made to other nocturnal animals (especially primates) where relevant. But before dealing with the animals themselves in detail, we will define what is meant by a nocturnal lifestyle and explore the illumination of nocturnal visual scenes.

2.05.2 What Is a Nocturnal Lifestyle?

For the purpose of answering this question, Martin G. R. (1990) very conveniently defined night as being the period of time between sunset and sunrise, and strictly nocturnal animals as those animals that execute all the waking activities of daily life during the same period of time. Thus, according to this definition, all animals that have only part of their waking activities during this period are not considered to be nocturnal, and this includes those active both night and day (referred to as cathemeral animals). In contrast, those active only for short periods of time during the dusk and dawn (i.e., crepuscular animals, including many species of dung beetles) are considered nocturnal. Despite being nocturnal, these animals may experience reasonably high light levels. As Martin carefully points out, this definition, whilst very convenient, does not imply anything about the light levels experienced by animals at night. As we will see below, even at one location and over a limited number of days, nocturnal light levels can vary over an enormous range. If one then adds the complications of latitude and time of year, then the variation is even greater: an animal in the polar summer experiences vastly brighter light levels at midnight than does an equatorial rainforest animal at the same longitude and moment in time.

Martin's definition of nocturnality is nonetheless very useful, and it is that which I adopt in this review: when discussing nocturnal vision, I will restrict my analysis to those species that are strictly nocturnal, that is, to those that carry out the waking activities of daily life entirely within the time interval between sunset and sunrise. I will nevertheless describe visual adaptations found in many diurnal species in order to highlight those found in nocturnal species.

2.05.3 Nocturnal Visual Scenes

2.05.3.1 Light Intensity

The intensity of light that reaches an eye in a natural setting depends on many factors (see Martin, G. R., 1990, for an excellent discussion). The first and most obvious of these is the time of day that the eye views the scene: at any one location, the transition from a bright sunny day to a clear night lit by a full moon brings with it a change in light intensity of around 5–6 orders of magnitude. If instead the night sky is clear and moonless, light levels are lower by a further 100 times (Lythgoe, J. N., 1979). Other factors that affect the intensity of natural light include the presence of clouds (which can reduce intensity by up to a factor of 10) and/or whether an animal is located under the closed canopy of a forest (which can reduce intensity by up to a factor of 100). Thus, the light intensity difference between an open sunny meadow on a clear summer day and the floor of a dense rainforest on a moonless and heavily overcast night could be up to 11 orders of magnitude (Martin, G. R., 1990; Figure 2). If we further use the Martin (1990) definition of night as the period of time between sunset and sunrise, then nocturnal light levels account for 8 of these 11 orders of magnitude. This clearly indicates that nocturnal animals (which in this definition also includes crepuscular animals) can experience an extremely wide range of light levels when compared with their diurnal relatives. As we shall see, this has led to the evolution of eyes that are specialized for different windows of nocturnal light intensity, with those adapted to dimmer light levels being considerably more sensitive.

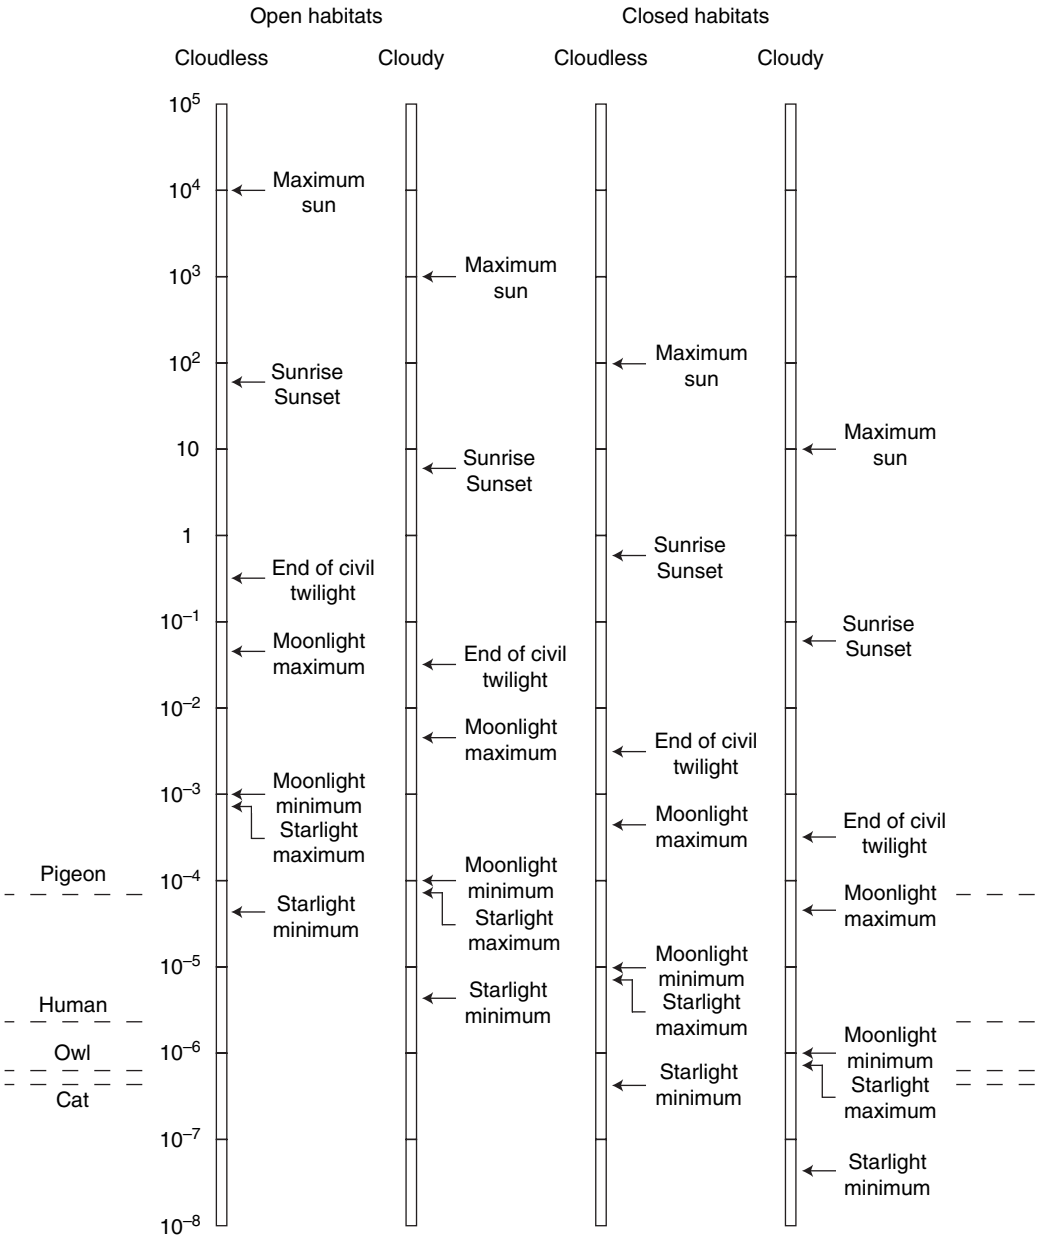

Figure 2 The luminance (in units of cd m^{-2}) of a natural substrate of leaf litter when illuminated by sunlight, moonlight, or starlight during cloudy and cloudless conditions. The luminance is shown for two habitat conditions: an open treeless field and beneath the closed canopy of a forest (which is considered here to reduce illumination by 100 times). Luminance is calculated assuming that the leaf litter substrate has an average reflectance of 25% and a fully overcast sky reduces illumination by a factor of 10. Dashed lines show absolute visual thresholds measured for pigeons, humans, tawny owls, and cats. Civil twilight is defined as the period during which the sun's disk is between the horizon and 6° below the horizon. Adapted with kind permission from Martin, G.R. 1990. Birds by Night. T. & A.D. Poyser.

2.05.3.2 Light Spectrum

Sunlight – the major source of light on earth – illuminates either directly, as during the day, or indirectly by reflection from the moon at night. The spectra of sunlight and moonlight, and the colors of objects seen under the two illuminations, are thus similar (Figure 3). However, on moonless starlit nights the spectrum is significantly red-shifted, a phenomenon that has implications for color vision at night (Johnsen, S. *et al.*, 2006).

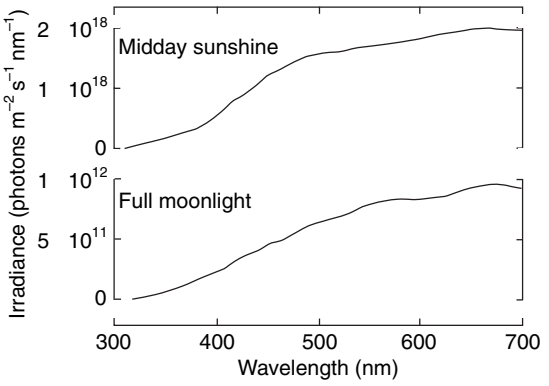

Figure 3 The irradiance spectra of sunlight and moonlight. The two spectra are similar, but moonlight is about a million times dimmer. Adapted from data given in Moon P. (1940) and Lythgoe J. N. (1979). From Warrant, E.J. 2004. Vision in the dimmest habitats on earth. J. Comp. Physiol. A. 190, 765–789.

2.05.3.3 Polarization

Due to the scattering of sunlight from particles in the atmosphere, the dome of the sky contains a circular pattern of polarized light centered on the sun, a pattern that many animals, especially invertebrates, are able to see and to use as a navigational compass cue. Within this pattern, the degree of polarization is greatest for light emitted from regions of the sky lying on a circular locus 90° from the sun (for review, see Waterman, T. H., 1981; Wehner, R., 1981), and the pattern moves with the sun during the course of the day. At sunset (or sunrise), when the sun is at the horizon, the polarization pattern is very simple, with the full sky emitting light polarized in a single direction. The degree of polarization is greatest across the zenith of the sky, up to 85% (Waterman, T. H., 1981; Cronin, T. W. *et al.*, 2006), the highest value attained during the day. Once the sun slips below the horizon, the degree of polarization declines, reaching negligible values at astronomical twilight when the sun is 18° below the horizon (Rozenberg, G. V., 1966).

For identical reasons, light from the moon also produces a circular pattern of polarized light, a fact we did not appreciate until recently (Gál, J. *et al.*, 2001). Apart from its intensity – which is a million times dimmer – the pattern of polarized light formed around the full moon is identical in structure to that formed around the sun. When the moon is in its first or last quarter, the pattern's intensity is a further 10 times dimmer.

2.05.4 Noise and the Reliability of Vision in Dim Light

2.05.4.1 Sources of Visual Noise

The greatest challenge for an eye that views a dimly illuminated scene is to absorb sufficient photons of light to reliably discriminate it (Laughlin, S. B., 1990). Because the arrival and absorption of photons is stochastic (and governed by Poisson statistics), quantum fluctuations set an upper limit to the visual SNR (Rose, A., 1942; De Vries, H., 1943). If we say that a photoreceptor absorbs N photons during one visual integration time, then it will experience an uncertainty – or photon shot noise – of $\sqrt{N}$ photons associated with this sample, that is, $N \pm \sqrt{N}$ photons (Rose, A., 1942; De Vries, H., 1943; Land, M. F., 1981; Warrant, E. J. and McIntyre, P. D., 1993; Warrant, E. J., 2004; 2006). This noise reduces the reliability of intensity discriminations and thereby the ability of the eye to distinguish contrast details in a scene. The SNR ($N/\sqrt{N} = \sqrt{N}$) thus improves with increasing photon catch, implying that photon shot noise, and contrast discrimination, is worse at lower light levels. This is the famous Rose–de Vries or square root law of visual detection at low light levels: the visual SNR, and thus contrast discrimination, improves as the square root of photon catch. As we shall see below, the eyes of nocturnal animals are usually adapted to capturing and absorbing as many photons as possible, thereby maximizing this SNR.

In addition to this external or extrinsic source of noise, there are also two internal or intrinsic sources of noise that further degrade visual discrimination by photoreceptors in dim light. The first of these, referred to as transducer noise, arises because photoreceptors are incapable of producing an identical electrical response, of fixed amplitude, latency, and duration, to each (identical) photon of absorbed light. This source of noise, originating in the biochemical processes leading to signal amplification, degrades the reliability of vision (Lillywhite, P. G. and Laughlin, S. B., 1979; Lillywhite, P. G., 1981; Laughlin, S. B. and Lillywhite, P. G., 1982). The second source of intrinsic noise, referred to as dark noise, arises because the biochemical pathways responsible for transduction are occasionally activated – even in perfect darkness (Barlow, H. B., 1956). These activations are due either to spontaneous conversion of rhodopsin to metarhodopsin or to spontaneous activation of G-protein-coupled steps in the transduction chain. Irrespective of their origin,

these activations produce dark events, electrical responses that are indistinguishable from those produced by real photons, and these are more frequent at higher retinal temperatures. At very low light levels, this dark noise can significantly contaminate visual signals. In insects and crustaceans, dark events are rare, only around 10 every hour at 25 °C (Lillywhite, P. G. and Laughlin, S. B., 1979; Dubs, A. *et al.*, 1981; Doujak, F. E., 1985). But in nocturnal toad rods, the rate is much higher – 360 per hour at 20 °C (Baylor, D. A. *et al.*, 1980) – and this sets the ultimate limit to visual sensitivity (Aho, A.-C. *et al.*, 1988; 1993).

2.05.4.2 A Trade-Off between Resolution and Sensitivity

Like the pixels of a digital camera, the density of detectors in an eye sets the finest spatial detail that can be reconstructed: more densely packed detectors can reconstruct finer details. This, however, is only true if the signals generated in neighboring detectors are significantly different. For a given eye radius, a greater density of smaller detectors means that each detector receives a smaller fraction of the available photons, and as we saw above, fewer photons lead to a noisier signal and a less reliable measurement of intensity. This leads in turn to fewer reliable levels of response to changes in intensity and thereby poorer contrast discrimination. In this case, the signals generated in neighboring detectors may not be significantly different, and the contrast differences inherent in the finer details may therefore remain unresolved. Thus, even though a greater density of smaller detectors has the potential for higher spatial resolution, the detectors risk being too insensitive to achieve it. This becomes more and more true as light levels fall.

This trade-off between resolution and sensitivity is nicely quantified by asking how much information can be extracted from a visual scene, that is, how many different pictures can be reconstructed by a matrix of visual channels (Snyder, A. W. *et al.*, 1977a; 1997b)? If there are p visual channels per unit solid angle of visual field, and each channel is capable of distinguishing i levels of intensity, then the maximum number of pictures that can be reconstructed is simply i^p. The natural logarithm of this number is the maximum spatial information capacity H of the eye (Snyder, A. W. *et al.*, 1977a; 1997b):

$$H = \ln i^p = p \ln i \qquad [1]$$

Equation [1] shows that a high amount of information can be extracted from a bright scene: the number of discriminable intensity levels (i) and the density of visual channels (p) can both be large. But as light levels fall, so too does the quantity of light captured by each channel. This in turn leads to an increase in the relative magnitude of the noise and a decline in both the SNR and the number of intensity levels that the channel can discriminate. The information capacity falls accordingly. One way of offsetting this loss is to somehow increase the amount of light reaching each visual channel. A common strategy is to decrease the density of channels and to widen their receptive fields, that is, to exchange spatial sampling density (reduced p) for an improved number of discriminable intensity levels (increased i).

Eyes with fewer channels, each having wider receptive fields and greater sensitivity, are a common feature of animals active in dim light. As we shall see below, specialized neural circuits may even perform spatial summation, the sole purpose of which is to increase sensitivity by coupling visual channels together to produce larger effective channels of lower density (Snyder, A. W., 1977; Laughlin, S. B., 1981a; Srinivasan, M. V. *et al.*, 1982; Laughlin, S. B., 1990; van Hateren, J. H., 1993; Warrant, E. J., 1999). In many animals, the trade-off between sampling density and signal levels may alter according to the ambient light intensity. For instance, some arthropods dark adapt by widening their rhabdoms and/or shortening their focal lengths at night (Leggett, L. M. W. and Stavenga, D. G., 1981; Williams, D. S., 1982; 1983; Nilsson, D.-E., 1989), while others experience migrations of screening pigments within the eye that widen the receptive fields of photoreceptors at night and narrow them again during the day (Autrum, H., 1981; Nilsson, D.-E., 1989; Land, M. F. and Osorio, D. C., 1990; Stavenga, D. G., 2004a; 2004b).

An unavoidable consequence of sacrificing spatial sampling density to improve the number of discriminable intensity levels is that vision becomes coarser. Reliable contrast discrimination becomes confined to a decreasing range of coarser image details as light levels fall, with all finer spatial details drowned by noise. The same information arguments apply to the resolution of contrasts in time. If a single photoreceptor views a moving object, then the photoreceptor's response will rise and fall as brighter and darker details of the object pass through the visual field. As the object moves faster, the ability of the photoreceptor to reliably code these contrast details declines due to the photoreceptor's finite response

speed (Srinivasan, M. V. and Bernard, G. D., 1975): the response of the photoreceptor is eventually too slow to collect sufficient light to support reliable contrast discrimination. The problem worsens as ambient light levels fall. The sufficient amount of light can only be collected from progressively slower objects. To compensate, vision generally slows down. This increases the SNR and improves contrast discrimination by suppressing photon noise at temporal frequencies that are too high to be reliably resolved (van Hateren, J. H., 1993). Just as in the spatial domain, reliable temporal contrast discrimination becomes confined to a decreasing range of slower image details as light levels fall, with all faster details drowned by noise. In other words, in terms of both space and time, the effects of noise confine vision to image details that are increasingly slower and coarser.

2.05.5 The Designs of Eyes and Their Sensitivity to Extended Scenes

2.05.5.1 The Eyes of Arthropods and Vertebrates

As the discussion above implies, the eyes of nocturnal animals are adapted both optically and neurally to capture as much of the available light as possible, thereby maximizing the amount of information that can be extracted from a dim nocturnal scene. This is equally true of compound eyes as of camera eyes, the two main eye designs we will deal with in this review (Figure 4).

Camera eyes (Figure 4(a)) have a retina that receives an image formed by an overlying lens and cornea. This eye design is possessed by all vertebrates, and also by many invertebrates, including cephalopods (squid and octopus) and arachnids (e.g., spiders, scorpions, and camel spiders). As we shall see below, the camera eyes of nocturnal vertebrates and arthropods are proportionately large and possess wide pupils, adaptations that maximize photon capture.

Compound eyes (Figures 4(b) and 4(c)) are chief organs of vision in most insects and crustaceans, and two major forms can be distinguished: apposition compound eyes (Figure 4(b)) and superposition compound eyes (Figure 4(c)). In apposition compound eyes (Figure 4(b)), each ommatidium is isolated from its neighbors by a sleeve of light-absorbing screening pigment, thus preventing light reaching the photoreceptive rhabdom from all but its own small corneal lens. This tiny lens – typically a few tens of micrometers across – represents the pupil of the apposition eye, and not surprisingly, this eye design is typical of insects and crustaceans living in bright habitats. Remarkable exceptions do exist, including nocturnal mosquitoes (Land, M. F. *et al.* 1997; 1999) and the nocturnal tropical halictid bee *Megalopta genalis* that we will discuss below. It is, however, the superposition eyes (Figure 4(c)) that are better known for their high sensitivity. In this eye design, typical of nocturnal insects and deep-sea crustaceans, the pigment sleeve is withdrawn, and a wide optically transparent area, the clear zone (*cz* in Figure 4(c)), is interposed between the lenses and the retina. This clear zone – and specially modified crystalline cones – allows light from a narrow region of space to be collected by a large number of ommatidia (comprising the superposition aperture) and to be focused onto a

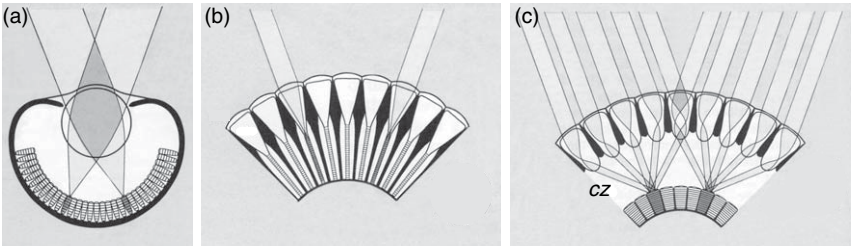

Figure 4 Three common eye designs. (a) A camera eye. Light is focused by the cornea (air only) and lens to form an image on the retina. (b) A focal apposition compound eye. Light reaches the photoreceptors exclusively from the small corneal lens located directly above. This eye design is typical of day-active insects. (c) A refracting superposition compound eye. A large number of corneal facets and bullet-shaped crystalline cones collect and focus light – across the clear zone of the eye (*cz*) – toward single photoreceptors in the retina. Several hundred, or even thousands, of facets service a single photoreceptor. Not surprisingly, many nocturnal arthropods have refracting superposition eyes, and benefit from the significant improvement in sensitivity. Courtesy of Dan-Eric Nilsson.

single rhabdom. Unlike the crystalline cones of most apposition eyes, those of superposition eyes have evolved refractive index gradients (in refracting superposition eyes), or reflecting surfaces (in reflecting superposition eyes), or a combination of both (in parabolic superposition eyes). These optical modifications allow as many as 2000 lenses to collect light for a single photoreceptor (as in some nocturnal moths). The width of this superposition aperture – which effectively acts as the pupil of the eye – is much larger than the width of a single corneal facet lens and represents a massive improvement in sensitivity.

2.05.5.2 The Optical Sensitivity of Eyes to Extended Scenes

The eyes of nocturnal animals, straining to see well in a dim extended world, are typically large relative to head size in order to maximize the area of the pupil and the sensitivity of the eye (Walls, G. L., 1942; Hughes, A., 1977). In addition to a large pupil, sensitivity to a dim extended scene is also improved by having visual channels with wide receptive fields. The wider the receptive field, the larger the region of the scene that the visual channel views, and the greater the number of photons it captures. Of course, spatial resolution is consequently compromised (Warrant, E. J. and McIntyre, P. D., 1992), but as we have implied above, this trade-off is typical of animals that view dim extended scenes.

These features of eyes are encapsulated in the Land sensitivity equation (Kirschfeld, K., 1974; Land, M. F., 1981), which describes the optical sensitivity S of an eye (in units of μm^2 sr) to an extended scene of broad spectral content (Warrant, E. J. and Nilsson, D.-E., 1998), as found in terrestrial habitats

$$S = \left(\frac{\pi}{4}\right)^2 A^2 \left(\frac{d}{f}\right)^2 \left(\frac{kl}{2.3 + kl}\right) \qquad [2]$$

Thus, good sensitivity to an extended scene results from a pupil of large area ($\pi A^2/4$), and photoreceptors each viewing a large solid angle ($\pi d^2/4f^2$ steradians) of visual space and absorbing a substantial fraction of the incident light ($kl/(2.3 + kl)$ for broad-spectrum light). Here A is the diameter of the pupil, f the focal length of the eye, and d and l the diameter and length of the photoreceptors, respectively. k is the peak absorption coefficient of the visual pigment. If all lengths have units of μm, then the unit of k is μm^{-1}. As recently pointed out by Stavenga D. G. (2003), the Land sensitivity equation, despite its great usefulness, does have some limitations, especially for photoreceptors behaving as waveguides and for certain eye designs of lower F-number.

A slightly more useful demonstration of sensitivity is to estimate the number of photons N that are absorbed by a photoreceptor from an extended scene during one integration time Δt. By calculating the number of absorbed photons, we can obtain an impression of the reliability of vision ($N \pm \sqrt{N}$), as well as the visual SNR ($\sqrt{N}$). N is obtained by multiplying the optical sensitivity of the eye S (μm^2 sr) with the intensity L (photons $\mu m^{-2} s^{-1} sr^{-1}$) of the light spectrum being viewed (Snyder, A. W., 1977; 1979; Warrant, E. J. and Nilsson, D.-E., 1998; Warrant, E. J., 1999; Kelber, A. *et al.*, 2002):

$$N = 1.13\left(\frac{\pi}{4}\right)\Delta\rho^2 A^2 \kappa \tau \Delta t \int \left(1 - e^{-kR(\lambda)l}\right) I(\lambda) d\lambda \qquad [3]$$

We have now replaced the solid angle of visual space viewed by a photoreceptor ($\pi d^2/4f^2$ steradians in eqn [2]) with the solid angular subtense of its (assumed) Gaussian receptive field ($\pi\Delta\rho^2/2.77 = 1.13\Delta\rho^2$, where $\Delta\rho$ is the angular half-width of the receptive field (or acceptance angle) in radians: Snyder, A. W., 1977; Laughlin, S. B. *et al.*, 1980). Other parameters in eqn [3] include the quantum efficiency of transduction κ and the transmission of the optics τ. The integral term describes the number of photons that will be absorbed by a photoreceptor viewing a radiance spectrum of quantal intensity $I(\lambda)$ with a resident visual pigment that has a normalized absorption spectrum $R(\lambda)$, where λ is wavelength. This integral is calculated between two wavelength limits: λ_1 and λ_2 (Warrant, E. J. and Nilsson, D.-E., 1998). λ_1 is set at 280 nm, the lowest wavelength likely to be seen by any animal (because the relative intensity of daylight below this wavelength is very low, and the internal structures of the eye absorb all wavelengths that are shorter). λ_2 is the wavelength at which the spectral sensitivity $R(\lambda)$ falls to 1% of its maximum at its long wavelength end. $R(\lambda)$ is given by the rhodopsin template of Stavenga D. G. *et al.* (1993). In this template, $\lambda_2 = 1.231\lambda_{max}$, where λ_{max} is the absorbance peak wavelength of the visual pigment.

2.05.6 Vision and Visual Behavior in Nocturnal Arthropods

The compound eyes and camera eyes of nocturnal arthropods – for example, insects, spiders, and crustaceans – are among the most sensitive found in the animal kingdom (Meyer-Rochow, V. B. and Nilsson,

H. L., 1998; Warrant, E. J., 2004; 2006). These eyes support an impressive repertoire of visual behaviors at night, including the ability to distinguish colors, to detect faint movements, to learn visual landmarks, to orient to the faint polarization pattern produced by the moon, and to navigate using the constellations of stars in the sky.

2.05.6.1 Optical Adaptations for Increased Sensitivity in Arthropods

As we discussed earlier (see Section 2.05.5.2), the optical structures of nocturnal eyes, irrespective of their type, are adapted for increased light capture in dim light. These adaptations are encapsulated in eqns [2] and [3]: larger eyes with larger pupils, having individual visual channels with large receptive fields, capture more of the available light. As we shall see, these are features of all nocturnal eyes, including arthropods.

2.05.6.1.1 Spider camera eyes

For their size, spiders have excellent vision, and many species – especially jumping spiders – have outstanding spatial resolution and the ability to distinguish color (Land, M. F., 1981; 1985). Their eyes are of the camera type, with well-developed corneal lenses that in many species can focus sharp aberration-free images on the underlying retina. This is also true of the large number of spiders with strict nocturnal activity, many of which are skillful visual hunters.

The nocturnal net-casting spider *Dinopis subrufus* is an excellent example (Figure 5(a); Blest, A. D. and Land, M. F., 1977). The posteromedial (PM) eyes of this formidable nocturnal hunter have lenses that can reach 1.4 mm in diameter, the largest known for a terrestrial arthropod, suggesting eyes with extreme sensitivity. This wide lens has a comparatively short focal length f, around 0.8 mm, which primarily improves sensitivity by widening the receptive fields of the visual channels (eqn [2]). The ratio of these two parameters – focal length f and lens diameter A – is frequently used to describe the light-gathering capacity of a lens. This ratio (f/A), known as the F-number, is also a useful and an easy metric for comparing the light-gathering capacities of different eyes (Warrant, E. J. and McIntyre, P. D., 1991), with a lower F-number indicating a brighter image (Table 1). *Dinopis* has an F-number of less than 0.6 (0.8/1.4), a much lower value than in the anteromedian (AM) eyes of the diurnal jumping spider *Phidippus johnsoni*, which have lenses of 0.38 mm diameter and an F-number of 2.0 (Land, M. F., 1981). The dark-adapted human eye has an

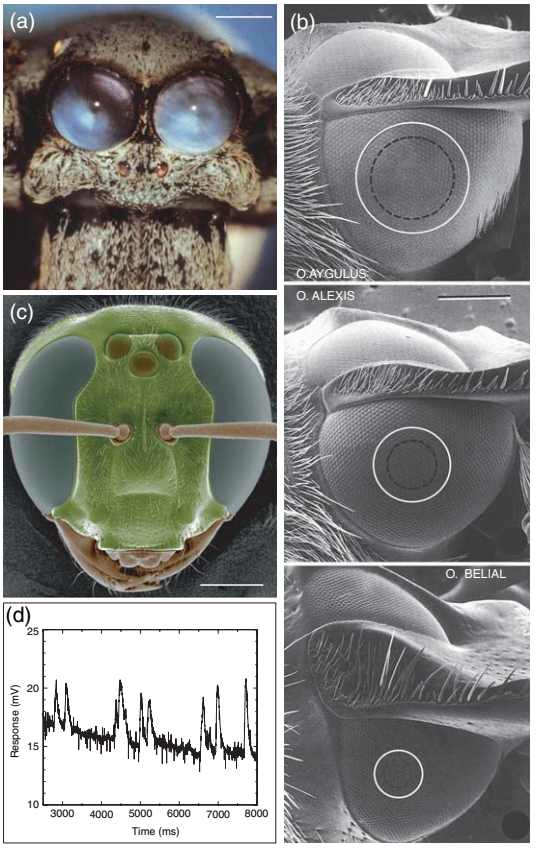

Figure 5 Nocturnal vision in arthropods. (a) The large posteromedial eyes of the nocturnal net-casting spider *Dinopis subrufus*, which have an F-number of 0.6. (b) The size of the superposition aperture in three species of onitine dung beetles: the nocturnal *Onitis aygulus* (upper panel), the crepuscular *Onitis alexis* (middle panel), and the diurnal *Onitis belial* (lower panel). The circular superposition aperture is indicated in white on the surface of each eye. The dashed circles refer to effective apertures, theoretically derived apertures in which each facet contributes light equally. In reality, facets near the edge of the aperture contribute less light than those near the center. Note how the superposition aperture is smaller in beetles from brighter habitats. (c) The head of the nocturnal halictid bee *Megalopta genalis* whose sensitive eyes allow them to forage at night. (d) Photoreceptor responses (bumps) to single photons of light in the nocturnal spider *Cupiennius salei*. Scale bar = 1 mm (a, c), 0.5 mm (a, d). (a) Adapted from Sinclair, S. 1985. How Animals See, Facts on File Publications. (b) From McIntyre, P.D. and Caveney, S. 1998. Superposition optics and the time of flight in onitine dung beetles. J. Comp. Physiol. A. 183, 45–60. (c) Scanning electron microscope image: Rita Wallén. (d) Pirhofer-Walzl, K., Barth, F.G., and Warrant, E.J. (in preparation).

F-number of around 2.1. Thus, the eyes of *Dinopis* are clearly constructed for high sensitivity.

The difference in optical sensitivity between these two spiders is not restricted to their lenses. Despite having similar focal lengths (~770 μm), their

F-number, the ratio of focal length to aperture (pupil) diameter, is calculated for the dark-adapted state in selected species. N, nocturnal; D, diurnal; C, crepuscular; Cam, camera eye; Sup, superposition eye; App, apposition eye. Superscript letters: *a* = posterior medial (PM) eye; *b* = posterior medial (AL) eye; *c* = values taken from frontal eye; *d* = since values given by Pettigrew (reference 8) were mostly calculated using fixed material, posterior nodal distance was used instead of focal length (estimated as 0.6 × anteroposterior eyeball distance) and corneal diameter was used instead of pupil diameter. This may have led to lower absolute values than found by other authors (e.g., note the case of the oilbird), but relative comparisons between nocturnal and diurnal birds are still valid using this method; *e* = *F*-number calculated using Pettigrew's method, except using actual pupil diameter instead of corneal diameter; *f* = may be nocturnal and diurnal during the breeding season; *g* = nocturnal only in winter; *h* = *F*-numbers for all primates calculated using Pettigrew's method (see note corresponding to letter *d*) using data in reference 12. References: 1 = Blest A. D. and Land M. F. (1977); 2 = Warrant E. J. (unpublished); 3 = Cleary P. *et al*. (1977); 4 = McIntyre P. D. and Caveney S. (1998); 5 = Greiner B. *et al*. (2004a); 6 = Land M. F. (1969); 7 = Warrant E. J. *et al*. (1999); 8 = Pettigrew J. D. (1982); 9 = Martin G. R. (1994); 10 = references given in Rojas L. M. *et al.* (2004); 11 = Martin G. R. *et al*. (2004a; 2004b); 12 = Kirk E. C. (2006).

rhabdoms differ greatly in width: 20 μm in the dark-adapted *Dinopis* (Blest, A. D. and Land, M. F., 1977) but only 2 μm in *Phidippus* (Land, M. F., 1969; 1985). This tenfold difference means that the rhabdoms of *Dinopis* view solid angular regions of space that are about 100 times larger than those viewed by the rhabdoms of *Phidippus*. These large fields of view, together with their much wider lenses (1.4 vs. 0.4 mm), endow *Dinopis* with an optical sensitivity of 101 μm^2 sr, compared to just 0.038 μm^2 sr in *Phidippus* (eqn [2]). Thus, compared to *Phidippus*, *Dinopis* has clearly traded resolution for sensitivity. This difference in optical sensitivity between nocturnal and diurnal spiders is reflected in electrophysiological measurements of the number of axial photons (from a point source) that are required to generate a half-maximal response (called the PAQ_{50}) in the photoreceptors. In *Dinopis* PM eyes, $PAQ_{50} = 5 \times 10^5$ photons (Laughlin, S. B. *et al*., 1980), whereas in the posterolateral (PL) eyes of the diurnal jumping spider *Plexippus* $PAQ_{50} = 7 \times 10^{10}$ photons (Hardie, R. C. and Duelli, P., 1978). About 100 000 times more photons are required to generate a half-maximal response in the diurnal spider!

Even though *Phidippus* has an outstanding resolution for an animal of its size (Land, M. F., 1985), resolution in *Dinopis* is still impressive: electrophysiologically measured angular sensitivity functions in *Dinopis* have a half-width (i.e., acceptance angle $\Delta\rho$) of only 2.3° (Laughlin, S. B. *et al*., 1980), a value narrower than in nearly all nocturnal insects (which also generally have much lower sensitivity). The eyes of *Dinopis* are not only exquisitely sensitive, they also have excellent resolution, qualities that no doubt assist them during nocturnal hunting.

2.05.6.1.2 Insect compound eyes

Many of the same kinds of mechanisms used in camera eyes to improve sensitivity to a dim extended scene are also found in compound eyes. In apposition compound eyes (Figure 4(b)), each ommatidium is isolated from its neighbors by a sleeve of light-absorbing screening pigment, thus preventing light reaching the photoreceptors from all but its own small corneal lens. This tiny lens – typically a few tens of micrometers across – represents the pupil of the apposition eye, and not surprisingly, this eye design is typical of insects and crustaceans living in bright habitats. Remarkable exceptions do exist, including nocturnal mosquitoes (Land, M. F. *et al*., 1997; 1999) and the nocturnal tropical halictid bee *M. genalis* that we will discuss below.

However, it is the superposition design that is better adapted for vision in dim light. As we saw in The Eyes of Arthropods and Vertebrates, the superposition aperture plays a dominant role in setting the sensitivity of the eye, and its size is adapted to the light intensity that the eye normally encounters. This can be seen in the superposition eyes of dung beetles from the single genus *Onitis* (McIntyre, P. D. and Caveney, S., 1998; Figure 5(b)). Individual species fly in search of dung at different times of day. The superposition apertures of nocturnal species (width $A = 845$ μm in *O. aygulus*) are considerably larger than those of crepuscular species ($A = 655$ μm in *O. alexis*). These in turn are more than twice as large as those of diurnal species ($A = 309$ μm in *O. belial*). Moreover, the nocturnal species *O. aygulus* has huge contiguous rhabdoms (13 μm wide × 86 μm long) compared to the diurnal species *O. belial* where they are small (6.5 μm × 32 μm) and

widely spaced. And unlike *O. aygulus*, diurnal species like *O. belial* also have sheaths of screening pigment around their rhabdoms, which cuts down light flux even more (Warrant, E. J. and McIntyre, P. D., 1991). These differences are reflected in the sensitivities (S) of their eyes (eqn [2]): $S = 59\,\mu m^2\,sr$ in *O. aygulus* but only $1.5\,\mu m^2\,sr$ in *O. belial*.

The highly visual hawkmoths (Sphingidae) – which hover in front of flowers and suck nectar on the wing – all have superposition eyes and a well-developed tapetum, irrespective of whether they are nocturnal or diurnal. The remarkable superposition eyes of the diurnal hummingbird hawkmoth *Macroglossum stellatarum* have diffraction-limited optics, and local retinal acute zones that are unique for the superposition design (Warrant, E. J. *et al.*, 1999), and like honeybees, they also locate flowers using full trichromatic color vision (Kelber, A. and Hénique, U., 1999). Most hawkmoths, however, are active in dim light, such as the nocturnal elephant hawkmoth *Deilephila elpenor* Figure 9(a). The superposition aperture in the frontal eye region of *Deilephila* contains 947 facets, considerably more than the 340 facets found in *Macroglossum*. With a focal length of 675 μm, and photoreceptors of width 10.3 μm (Warrant, E. J., unpublished data), *Deilephila* achieves an optical sensitivity of $69\,\mu m^2\,sr$. In *Macroglossum*, on the other hand, the value is just over half of this – $38\,\mu m^2\,sr$ – a very high sensitivity for a diurnal eye (focal length 409 μm, rhabdom diameter 7.7 μm: Warrant, E. J. *et al.*, 1999). Since both hawkmoths have a similar receptive field size ($d/f \approx 1^\circ$), the better sensitivity in *Deilephila* is entirely due to its larger superposition aperture, a sensitivity that is sufficient to allow *Deilephila* to see color at night, the first animal known that can (Kelber, A. *et al.*, 2002; see Section 2.05.6.3.2).

Despite having apposition eyes, many bees (Greiner, B. *et al.*, 2004a; Warrant, E. J. *et al.*, 2004), wasps (Greiner, B., 2006), and ants (Menzi, U., 1987; Moser, J. C. *et al.*, 2004) have adopted nocturnal lifestyles to take advantage of reduced competition and predation. The Central American halictid bee *M. genalis* (Figure 5c) is an excellent example. This bee can visually learn and use landmarks for homing at night, an impressive feat considering the size and design of its eyes (Warrant, E. J. *et al.*, 2004). *Megalopta* is a facultatively social bee, with females living in groups of up to 10 in long bored-out sticks (Janzen, D. H., 1968; Arneson, L. and Wcislo, W. T., 2003; Wcislo, W. T. *et al.*, 2004). Each day, bees emerge twice from the nest to forage, each trip lasting up to about 35 min (Kelber, A. *et al.*, 2006). The first foraging trip begins up to an hour before dawn, and the second ends about 40 min after sunset, when light levels under the thick rainforest canopy are similar to starlight levels above. This behavior contrasts strongly with the European honeybee *Apis mellifera*, which is strictly day active. Not surprisingly, this contrast is also reflected in the structure and sensitivity of the eyes. Even though *Megalopta* has larger eyes and larger facets than in *Apis* (facets diameters up to 36 μm, compared to just 20 μm), the biggest difference between the two species lies in the size of the rhabdoms (Greiner, B. *et al.*, 2004a; Warrant, E. J. *et al.*, 2004). These have a width of only 2 μm in *Apis*, but in *Megalopta* they reach an extraordinary 8 μm, resulting in a receptive field of more than seven times greater solid angular extent. Similar adaptations are also found in the nocturnal wasp *Apoica pallens* (Greiner, B., 2006). These differences in receptive field and facet size allow *Megalopta* an optical sensitivity that is almost 30 times greater than in *Apis*: 2.7 versus $0.1\,\mu m^2\,sr$. Even though this is a significant improvement over *Apis*, sensitivity is still very modest compared to *Deilephila* ($69\,\mu m^2\,sr$) or *Dinopis* ($101\,\mu m^2\,sr$). This comparison shows up the inherent limitations of the apposition design for vision in dim light and begs the question – how can *Megalopta* nonetheless navigate using landmarks at night? The answer, we believe, lies in the optic lobe, a possibility we explore in Spatial and temporal summation.

2.05.6.2 Neural Adaptations for Increased Sensitivity in Arthropods

Arthropods are generally small animals and thus bear small eyes. Even though many nocturnal arthropods (especially nocturnal spiders) have considerable optical sensitivity, their small eyes on their own may still capture too few photons to support reliable vision. We have just highlighted this risk for the bee *M. genalis*. With only 30 times the optical sensitivity of its diurnal relatives, one might ask whether this is sufficient to explain its ability to see at night. The answer is probably no, and other mechanisms – particularly neural mechanisms – are likely to make up the short fall in sensitivity. Such mechanisms are already present at the level of the photoreceptors.

2.05.6.2.1 Signal transduction in nocturnal arthropod photoreceptors

Even if a nocturnal animal has very sensitive eyes that capture as many of the available photons as

possible, a reliable signal is only assured if each captured photon is transduced efficiently and reproducibly. This is the task of the photoreceptors, and signal reliability at this level depends on how ideal the receptors are as photodetectors. Even though arthropod photoreceptors are not perfectly ideal, suffering as we saw earlier from various sources of intrinsic noise, in many species they are nonetheless remarkably efficient.

Ever since the pioneering studies of Yeandle in the horseshoe crab *Limulus* in the late 1950s (Yeandle, S., 1958), we have known that photoreceptors can respond to single photons with small but distinct electrical responses known as bumps, responses found in both vertebrates and invertebrates (Figure 5(d)), both nocturnal and diurnal. Apart from the horseshoe crab, bumps have now been recorded from many invertebrates including insects (e.g., flies, locusts, and cockroaches; reviewed by Laughlin, S. B., 1990), crustaceans (e.g., Doujak, F. E., 1984), and spiders (e.g., Laughlin, S. B. *et al.*, 1980).

Despite this apparently remarkable sensitivity to single quanta of light, not all photons that strike the pupil of an eye are actually absorbed by the photoreceptors and lead to a bump. Due to reflections, screening pigments, waveguide effects, and visual pigment absorption efficiency, only a certain fraction of photons entering the pupil are transduced. In flies, the fraction is around 50% (Laughlin, S. B., 1990). In the shore crab *Leptograpsus variegatus*, it is 45% (Doujak, F. E., 1985) and in the locust *Locusta migratoria*, 59% (Lillywhite, P. G., 1977). In the nocturnal spider *D. subrufus*, the figure is likely to higher, around 74% (Blest, A. D., 1978; Laughlin, S. B. *et al.*, 1980). This capture efficiency is actually quite high: in vertebrates the figure tends to be somewhat lower, and in the cat it is probably below 25% (Barlow, H. B. *et al.*, 1971).

It has long been known that the bumps of nocturnal arthropods (e.g., those of nocturnal spiders: Laughlin, S. B. *et al.*, 1980) tend to be of much larger amplitude than those of diurnal species. Since there is (of course) no difference between photons available at night or during the day, larger bumps in nocturnal animals imply a higher transduction gain. The transduction gain sets the size of the response for a given step in stimulus intensity, an amplification mechanism that affects not only the amplitude of the response but also the amplitudes of any sources of noise. By itself, therefore, this photoreceptor amplification mechanism cannot provide an improvement in the visual SNR. However, recent work in nocturnal bees (Frederisken, R., Wcislo, W. T., and Warrant, E. J., in preparation) shows that the higher gain of nocturnal photoreceptors probably prepares the visual signal for a subsequent stage of neural processing, where spatial summation of signals from many converging photoreceptors may strongly enhance the signal but average out the noise (which is not correlated between photoreceptors). This summation, if it occurs, would thereby lead to a considerable improvement in the SNR (see next section), albeit at the cost of spatial resolution. Thus, even though an increased transduction gain (and large bumps) does not enhance visual reliability at the level of the photoreceptors *per se*, the enhancement probably manifests itself later as a result of spatial summation. How and where does this summation occur?

2.05.6.2.2 Spatial and temporal summation

Neural summation of light in space and time can significantly improve visual reliability in dim light (Snyder, A. W., 1977; Snyder, A. W. *et al.*, 1977a; 1977b; Laughlin, S. B., 1981a; 1990; Warrant, E. J., 1999). We have already mentioned summation in time above (see Section 2.05.4.2): when light gets dim, the visual systems of nocturnal animals can improve visual reliability by responding more slowly, either by having slower photoreceptors or by neurally integrating signals at a higher level in the visual system. But this only comes at a price: temporal summation can drastically degrade the perception of fast-moving objects, potentially disastrous for a fast-flying nocturnal animal that needs to negotiate obstacles! Not surprisingly, temporal summation is more likely to be employed by slowly moving animals.

Summation of photons in space can also improve image quality. Instead of each visual channel collecting photons in isolation (as in bright light), the transition to dim light could activate specialized laterally spreading neurons that couple the channels together into groups. Evidence of such neurons has been found in the first optic ganglion (lamina ganglionaris) of nocturnal cockroaches (Ribi, W. A., 1977), fireflies (Ohly, K. P., 1975), and hawkmoths (Strausfeld, N. J. and Blest, A. D., 1970), and these have been interpreted as an adaptation for spatial summation (Laughlin, S. B., 1981a). The nocturnal bee *M. genalis* also appears to have such neurons (Greiner, B. *et al.*, 2004b; 2005; Figure 6a). Each summed group – themselves now defining the

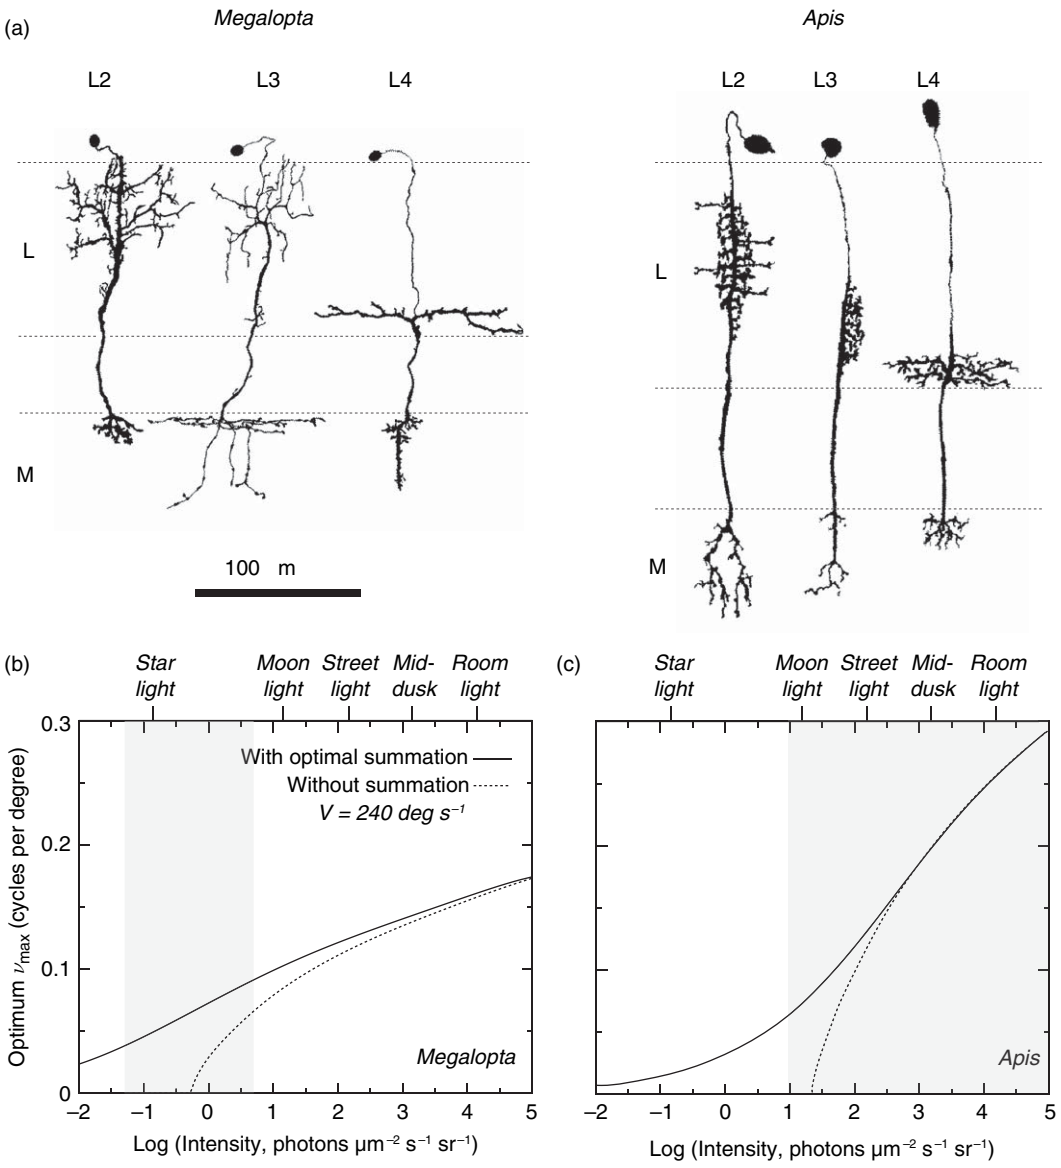

Figure 6 Spatial summation in nocturnal bees. (a) Comparison of the first-order interneurons – L-fiber types L2, L3, and L4 – of the *Megalopta genalis* female (left) and the worker honeybee *Apis mellifera* (right). Compared to the worker honeybee, the horizontal branches of L-fibers in the nocturnal halictid bee connect to a much larger number of lamina cartridges, suggesting a possible role in spatial summation. *L* = lamina, *M* = medulla. Reconstructions from Golgi-stained frontal sections. Adapted from Greiner B. *et al.* (2004b) and Ribi W. A. (1975). (b, c) Spatial and temporal summation modeled at different light intensities in *Megalopta genalis* (b) and *Apis mellifera* (c) for an image velocity of 240 °s^{-1} (measured from *Megalopta genalis* during a nocturnal foraging flight: Warrant, E. J. *et al.*, 2004). Light intensities are given for 540 nm, the peak in the bee's spectral sensitivity. Equivalent natural intensities are also shown. The finest spatial detail visible to flying bees (as measured by the maximum detectable spatial frequency, ν_{max}) is plotted as a function of light intensity. When bees sum photons optimally in space and time (solid lines), vision is extended to much lower light intensities (nonzero ν_{max}) compared to when summation is absent (dashed lines). Note that nocturnal bees can see in dimmer light than honeybees. Gray areas denote the light intensity window within which each species is normally active (although honeybees are also active at intensities higher than those presented on the graph).

channels – could collect considerably more photons over a much wider visual angle. The greatly enlarged receptive fields produced by this spatial summation result in a simultaneous and unavoidable loss of spatial resolution. Despite being much brighter, the image becomes necessarily coarser.

Spatial summation is likely to be widespread, as evidence from insects is now suggesting. Using

behavioral methods, Dubs A. *et al.* (1981) measured the threshold optomotor response of tethered flies that viewed a wide-field grating stimulus and in parallel recorded the rates of bump production at the same threshold intensity, both in the photoreceptors and in the first-order interneurons to which they connect. Using a point source centered in the field of view, the interneuron bump rate was found to be six times that of the photoreceptors – exactly the ratio expected, since six photoreceptors synapse onto one interneuron. However, when the point source was exchanged for the dim extended grating stimulus at threshold intensity, the interneuron bump rate increased to between 18 and 20 times the photoreceptor rate, implying that signals from several neighboring ommatidia were being summed at the interneuron (possibly via presynaptic summation between receptors). Spatial summation has also been found in the motion pathways that process the optomotor response in flies (Dvorak, D. and Snyder, A. W., 1978) and nocturnal hawkmoths (Warrant, E.J., O'Carroll, D. C., and Theobald, J. C., in preparation). In bright light, the elementary motion detectors of flies calculate motion by using signals generated in neighboring ommatidia. But as light levels fall, the elementary motion detectors calculate motion by comparing signals generated in successively more distant neighbors, up to two, three, or even four ommatidia apart (Pick, B. and Buchner, E., 1979). This increase in spatial summation is accompanied by a decrease in lateral inhibition (Srinivasan, M. V. and Dvorak, D. R., 1980).

Even though summation compromises spatial and temporal resolution, the gains in photon catch are so enormous that vision in dim light can be greatly improved. This is especially true in small eyes like those of arthropods. If a locust, an insect with apposition eyes, employs summation optimally, it has the potential to see reliably at light intensities up to 100 000 times dimmer than those in which they would normally become blind (Warrant, E. J., 1999). Like locusts, nocturnal bees would also benefit from optimal summation. Indeed, the wide lateral branches of its laminar monopolar cells L2, L3, and L4, which spread to 12, 11, and 17 lamina cartridges, respectively, are considerably wider than the homologous cells of *Apis*, which spread to 2, 0, and 4 cartridges, respectively (Greiner, B. *et al.*, 2004b; 2005; Figure 6(a)).

Even though their role in summation is yet to be shown, the morphologies of these cells in *Megalopta* are well suited to the task of summation. If one investigates the possible improvement afforded by optimal spatial and temporal summation using theoretical methods (Warrant, E. J., 1999), then both *Megalopta* (Figure 6(b)) and *Apis* (Figure 6(c)) are able to resolve spatial details in a scene at much lower intensities with summation than without it (Theobald, J. C. *et al.*, 2006). These theoretical results assume that both bees experience an angular velocity during flight of $240^{\circ}s^{-1}$, a value that has been measured from high-speed films of *Megalopta* flying at night. At the lower light levels where *Megalopta* is active, the optimum visual performance shown in Figure 6(b) is achieved with an integration time of about 30 ms and summation from about 12 ommatidia (or cartridges). This integration time is close to the photoreceptor's dark-adapted value (Warrant, E. J. *et al.*, 2004), and the extent of predicted spatial summation is very similar to the number of cartridges to which the L2 and L3 cells branch (Greiner, B. *et al.*, 2004b), thus strengthening the hypothesis that the lamina monopolar cells are involved in spatial summation.

Even in the honeybee *Apis*, summation can improve vision in dim light (Figure 6(c)). Interestingly, the Africanized race, *Apis mellifera scutellata*, and the closely related southeast Asian giant honeybee *Apis dorsata*, both forage during dusk and dawn, and even throughout the night, if a moon half-full or larger is present in the sky. Behavioral experiments show, however, that even the strictly day-active European honeybee is capable of seeing course habitat features, like large pale flowers, at moonlight intensities. This ability can be explained only if bees optimally sum photons over space and time (Warrant, E. J. *et al.*, 1996), and this is also revealed in Figure 6(c) (for an angular velocity of $240^{\circ}s^{-1}$). At the lower light levels where *Apis* is active, the optimum visual performance shown in Figure 6(c) is achieved with an integration time of about 18 ms and summation from about three or four cartridges. As in *Megalopta*, this integration time is close to the photoreceptor's dark-adapted value (Warrant, E. J. *et al.*, 2004), and the extent of predicted spatial summation is again very similar to the number of cartridges to which the L2 and L3 cells actually branch.

2.05.6.3 Visual Behavior in Nocturnal Arthropods

Arthropods clearly have many adaptations to increase sensitivity in dim light, and these allow nocturnal species to use vision to perform a number of important behavioral tasks.

2.05.6.3.1 Nocturnal navigation and homing

The nocturnal bee *M. genalis*, despite having eyes only 30 times as sensitive as those of a honeybee (see Section 2.05.6.1.2), is able to forage in a dark rainforest understory at night and return to its nest – a narrow hollowed-out stick in the undergrowth – without getting lost. This impressive feat is achieved visually. When *Megalopta* flies from its nest at night, it turns to face the nest entrance and begins to inspect the nest and other objects nearby in what is clearly an orientation flight (Figure 7(a)), a well-known phenomenon in diurnal bees such as the honeybee (Becker, L., 1958; Lehrer, M., 1996; Zeil, J. *et al.*, 1996; Capaldi, E. A. and Dyer, F. C., 1999). In honeybees, orientation flights are used to learn the arrangement of landmarks around the hive prior to departure, so that the hive entrance can be recognized and located upon return. Proof that *Megalopta* uses orientation flights to learn the arrangement of landmarks around the nest entrance was shown in a series of behavioral experiments (Figures 7(b) and 7(c); Warrant, E. J. *et al.*, 2004). Five nest sticks were placed beside one another on a small stand in the rainforest, and of these, only the middle nest was occupied (marked by a stars in Figures 7(b) and 7(c)). The bee left its nest at 18.48 (16 min after sunset), performed an orientation flight for a few seconds (presumably learning the spatial arrangement of the five nests), and then left (Figure 7(b), upper panel). While the bee was away, the positions of the bee's nest and an empty nest were swapped (Figure 7(b), lower panel). Upon return at 18.58, the bee flew without hesitation into the central unoccupied nest – the spatially correct nest – but after a couple of seconds flew out again. After resurveying the nests, the bee returned to the central nest, again immediately flying out. Presumably the aroma or some other feature of the nest was repellent to the bee, and it was not until the bee's actual nest was retuned to the central position that the bee ceased to reemerge. In a second experiment, a movable white card was instead used as a landmark – the bee's nest in this case remained in its original location. Prior to the bee's departure, the landmark was placed over the entrance of the central, occupied nest (Figure 7(c),

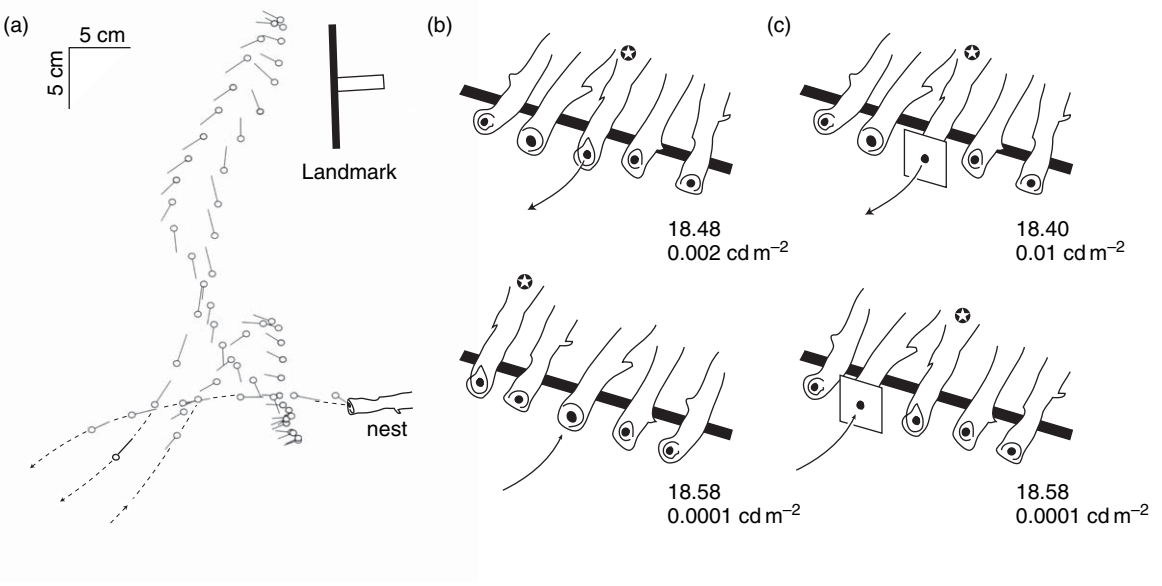

Figure 7 Nocturnal landmark orientation in the nocturnal halictid bee *Megalopta genalis*. (a) A typical nocturnal orientation flight, as seen from below. The bee leaves her nest and quickly returns to face the nest entrance. Flying in short arcs, she investigates the nest entrance and a neighboring landmark to learn their spatial arrangement before departing on her foraging trip. Each ball-and-stick represents the position of the head (ball) and body (stick) at 40 ms intervals. (b, c) Landmark learning. Bees leaving for a foraging trip learn the position of their nest relative to others (b) or learn the presence of a white square card attached to their nest (c). Upon return, bees enter the nest marked by the landmarks they have previously learned, not their actual nests (which are marked by stars). The rear side of the square card was attached to a Perspex cylinder that slipped neatly over the end of the nest stick to hold the card in place over the nest entrance. Times and light intensities at departure and return are also shown. From Warrant, E.J., Kelber, A., Gislén, A., Greiner, B., Ribi, W., and Wcislo, W.T. 2004. Nocturnal vision and landmark orientation in a tropical halictid bee. Curr. Biol. 14, 1309–1318.

upper panel). The bee departed its nest at 18.40, performed an orientation flight, and left. While the bee was away, the white card was placed over the entrance of a neighboring unoccupied nest. The bee returned at 18.58 and flew directly into the landmarked unoccupied nest (Figure 7(c), lower panel). As before, the bee flew out almost immediately, due to the foreign internal environment of the landmarked nest. This continued until the landmark was returned to the bee's actual nest, after which it no longer emerged. These two experiments show that *Megalopta* is capable of using landmarks at night to find their way home, an ability that can only be explained if these bees employ spatial and temporal summation at night (see Section 2.05.6.2.2). Similar abilities have now been found in the homing behavior of the giant nocturnal Indian carpenter bee *Xylocopa proximata* (Somanathan, H., Borges, R.M., Kelber, A., and Warrant, E.J., in preparation).

The sun, the moon, and the stars are well-known visual cues that help animals to navigate and to find their way home. Stars are point sources that vary considerably in their intensity from star to star. Eyes with greater sensitivity for point sources, that is, with wider pupils (eqns [2] and [3]), will see many more stars in the night sky than those with less sensitivity. The large 8 mm pupil of a dark-adapted human observer permits many thousands of stars to be seen, while for much smaller eyes and pupils, the number of visible stars will be a lot less. The apposition eyes of the shore crab – with corneal facet lenses 45 μm wide – will be limited to seeing the sky's 12 brightest stars (Doujak, F. E., 1985). Arthropods with superposition eyes, such as nocturnal moths, have the potential to see more stars, but as with the shore crab, the spatial resolving power of compound eyes may not be sufficient to accurately distinguish constellations. Nonetheless, the presence of a bright star, or a bright group of stars, within the visual field may act as a simple landmark during migration, as indeed seems to be the case for yellow underwing moths (Sotthibandhu, S. and Baker, R. R., 1979).

A more subtle landmark is the distinctive pattern of polarized light that is produced by the scattering of sunlight in the atmosphere. This pattern, symmetric around the sun and strongly visible to all animals with polarization vision, has long been known as a compass bearing that guides navigation in diurnal animals (Waterman, T. H., 1981; Wehner, R., 2001; Wehner, R. and Labhart, T., 2006). As we mentioned earlier (see Section 2.05.3.3), an identical but much dimmer pattern is also formed around the moon. Many animals have eyes of sufficient sensitivity to see the pattern and use it for navigation. One such animal is the crepuscular–nocturnal African dung beetle *Scarabaeus zambesianus* (Figure 8a; Dacke, M. *et al.*, 2003a; 2003b; 2004), whose dorsal superposition eyes (Figure 8(b)) have specialized polarization-sensitive regions (or dorsal rim areas (DRAs)) that analyze the polarization pattern of the moonlit night sky. The goal of this analysis is to help these beetles maintain a straight-line path while rolling a ball of dung away from the frenzied competition of the dung heap, the safest and most efficient route of escape. On moonlit nights (Figure 8(c)) *Scarabaeus* easily maintains a straight rolling path, whereas on moonless nights (Figure 8(d)) it cannot (on moonlit nights the moon's disk was obscured to ensure that it was unable to act as an orientation cue). This strongly suggests that polarized moonlight is the cue (Dacke, M. *et al.*, 2003a), a conclusion reinforced by experiments in which a UV-transmitting polarizing filter was placed directly over the rolling beetle (Figures 8(e) and 8(f)). With its transmission axis oriented perpendicularly to the dominant polarization direction of the moonlit night sky, the filter caused the beetle to turn by 90° (either to the left or to the right). Thus, *Scarabaeus*' small but very sensitive dorsal superposition eyes allow it to analyze the moon's dim polarization pattern and to orient with respect to it, the first animal known that can (Dacke, M. *et al.*, 2003a). Many other animals, notably nocturnally migrating insects and birds, may have a similar ability and utilize a celestial resource that until quite recently remained unknown. Nocturnal crickets, for instance, are prime candidates. Crickets have exquisite sensitivity to polarized light, with behavioral response thresholds occurring at even lower intensities than those of polarized moonlight (Herzmann, D. and Labhart, T., 1989; Labhart, T. *et al.*, 2001).

Another remarkable nocturnal navigator is the wandering spider *Leucorchestris arenicola* of southern Africa, a strictly nocturnal spider that prefers to leave its burrow in search of mates on moonless starlit nights (Nørgaard, T. *et al.*, 2003; Nørgaard, T., 2005; Nørgaard, T. *et al.*, 2006; 2007). Males search for females by leaving the burrow and meandering over large distances, often hundreds of meters. Nevertheless, they have no trouble finding their way home to the burrow. Careful experiments have ruled out olfactory and gravitational cues, leaving local visual landmarks, such as the shapes and locations of bushes, trees, and dunes in the vicinity of the

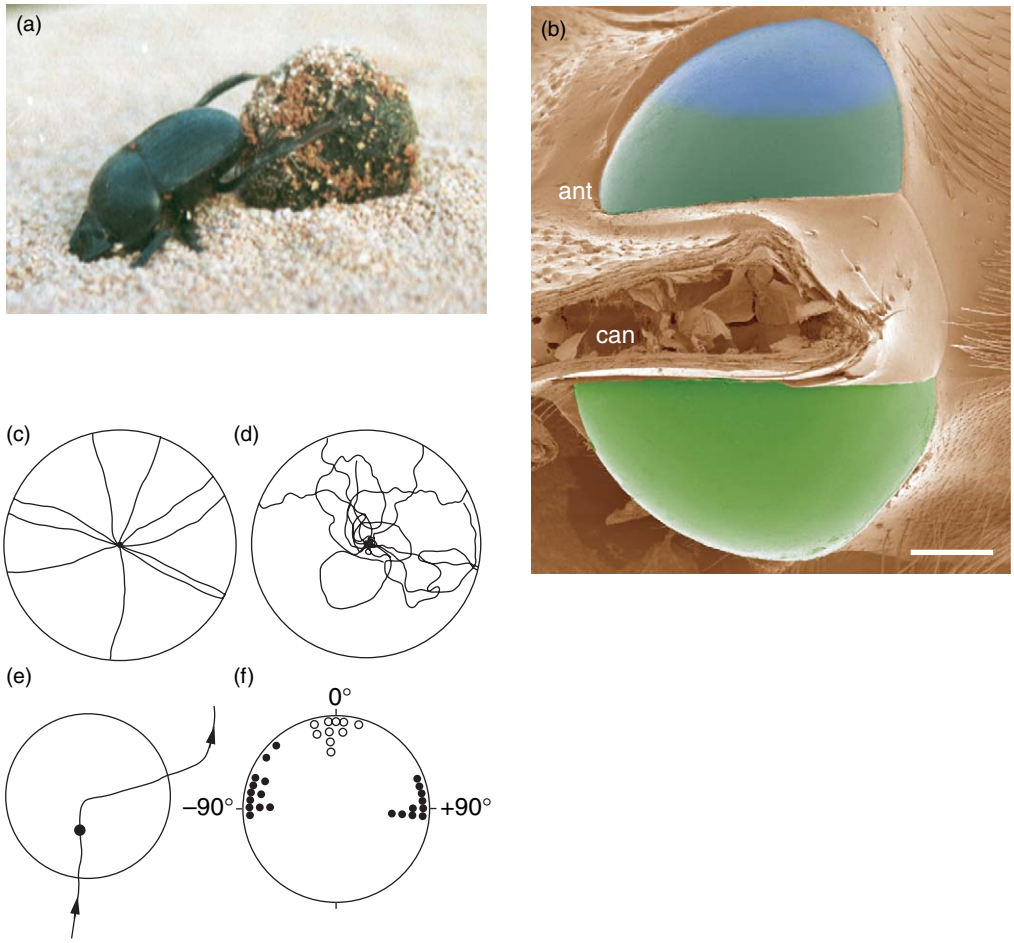

Figure 8 Polarization of moonlight and orientation in the dung beetle *Scarabaeus zambesianus*. (a) *Scarabaeus* rolling a ball of dung. (b) A false-color scanning electron micrograph of the left dorsal and ventral eyes. A canthus (*can*), here cut open to allow easier orientation, separates the two eyes. The blue region in the upper half of the dorsal eye indicates the dorsal rim area (or DRA), the region of the eye whose rhabdoms are specialized for the analysis of polarized light. In other parts of the dorsal eye, and throughout the ventral eye, the rhabdoms are unable to process polarized light (eye regions colored green). *ant* = anterior. Scale bar = 0.5 mm. (c) On a moonlit night, beetles orient along straight paths. (d) On moonless nights, beetles orient along random paths. (e) The change in direction (right turn, +70°) taken by a single rolling beetle when a perpendicularly polarizing filter is placed over the beetle at the position indicated by the *dot*. The beetle resumes its direction of travel on exposure to the open sky. The circle represents the extent of the 42 cm-diameter filter. (f) Average angles of turn made by 22 beetles when covered by the same filter as in E (filled circles, binned in 5° intervals): left turns, $-77° \pm 14.7°$; right turns, $87.9° \pm 9.3°$. Under a parallel polarizing filter, beetles did not deviate from their original direction (open circles). (a, c–f) Adapted from Dacke, M., Nilsson, D.-E., Scholtz, C.H., Byrne, M., and Warrant, E.J. 2003a. Insect orientation to polarized moonlight. Nature 424, 33. (b) Adapted from Dacke, M., Nordström, P., Scholtz, C.H. 2003b. Twilight orientation to polarised light in the crepuscular dung beetle *Scarabaeus zambesianus*. J. Exp. Biol. 106, 1535–1543.

burrow, as the most likely sensory basis for this homing behavior. However, spiders can sometimes return to the burrow using a bee-line trajectory. This suggests the use of path integration, a navigational mechanism that relies on celestial visual cues (such as polarized light), and which is known from diurnal insects such as the desert ant *Cataglyphis bicolor* (e.g., Wehner, R., 2003). Since polarized light information is not available when *Leucorchestris* is active, other cues must be responsible (such as the constellations of stars). Thus, even though vision is likely to drive homing behavior in *Leucorchestris*, this remains to be established with certainty.

2.05.6.3.2 Nocturnal color vision

As we mentioned above, the nocturnal world is just as rich in colors as the diurnal world (Figure 1), and we have recently begun to discover animals that have

sufficient visual sensitivity to distinguish them (Kelber, A. and Roth, L. S. V., 2006). The first such discovery was made in the nocturnal hawkmoth *D. elpenor* (which we discussed earlier). Like all hawkmoths so far investigated, *Deilephila* has three different spectral classes of photoreceptors, centered in the ultraviolet (350 nm), the violet (440 nm) and the green (525 nm) parts of the spectrum (Höglund, G. *et al.*, 1973; Schwemer, J. and Paulsen, R., 1973). The hummingbird hawkmoth *M. stellatarum* – *Deilephila*'s day-active cousin – has excellent trichromatic color vision based on these three spectral classes (Kelber, A. and Hénique, U., 1999; Kelber, A. *et al.*, 2003), and it has long been thought that *Deilephila* may also share this ability (Schlecht, P., 1979). After training *Deilephila* to associate a sugar reward with a blue disk (Kelber, A. *et al.*, 2002), the disk was placed within a series of other disks of equal size but of various shades of gray or of different colors (Figure 9(a)). These disks were placed on a uniform field of pale gray. With regard to the gray tones, these were deliberately made both lighter and darker in absolute brightness than the learned blue in order to test whether hungry moths use achromatic contrast cues, rather than color, to find the learned blue disk (Figures 9(b) and 9(c)).

The ability of trained *Deilephila* to distinguish the blue disk was tested in an arena illuminated by one of five intensities of broad-spectrum white light, ranging from 1 cd m^{-2} (mid-to-late dusk) to 10^{-4} cd m^{-2} (starlight). At all intensities, *Deilephila* discriminated the blue disk from all shades of gray with a choice frequency of at least 80%, even at starlight intensities (Figure 9(b)). When the training color was swapped to yellow, the results in starlight were similar (Figure 9(c)). Human observers, subjected to the same experimental conditions, succeeded in distinguishing the blue and yellow disks from the shades of gray only down to full-moon intensities (10^{-2} cd m^{-2}): at dimmer intensities light levels are too low for human color vision to function.

These results show that *Deilephila* is capable of discriminating colors in starlight, at light levels more than 100 times dimmer than the dimmest in which humans can do it. Using eqn [3], we can calculate the number of photons N absorbed by the green-, blue-, and UV-sensitive photoreceptors per integration time, when viewing the colored targets at the dimmest illuminating intensity (10^{-4} cd m^{-2}). Even though *Deilephila* has a very sensitive superposition eye, the photoreceptors only absorb between 1 and 16 photons per integration time for

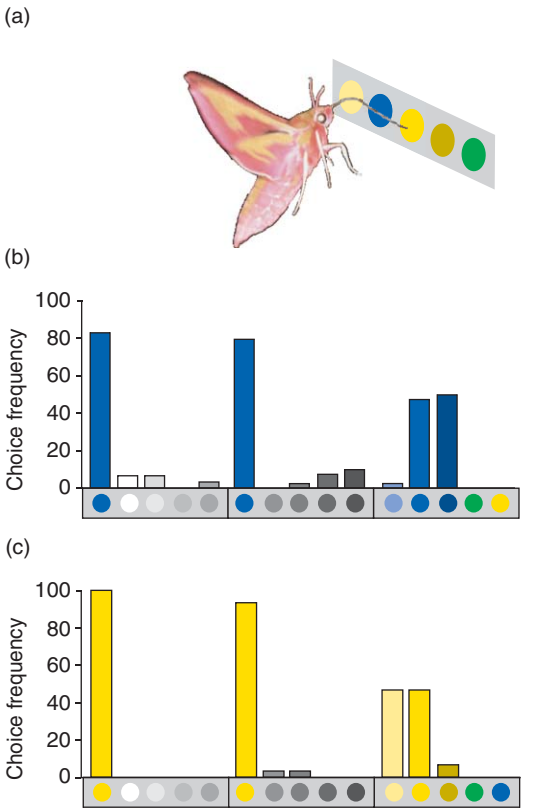

Figure 9 Color discrimination by the nocturnal hawkmoth *Deilephila elpenor.* In color discrimination experiments (a), the moth is required to choose a learned colored target from a selection of targets of various other colors. At starlight intensities, *Deilephila* is capable of discriminating a learned colored target (blue (b) or yellow (c)) from eight different shades of gray, but not from different shades of the same color. From Kelber, A., and Roth, L. S. V. 2006. Nocturnal colour vision – not as rare as we might think. J. Exp. Biol. 209, 781–788.

the gray shades and the various shades of blue (Kelber, A. *et al.*, 2002). This represents an *SNR* of between only 1 and 4 ($SNR = \sqrt{N}$, see above), which is insufficient to distinguish color reliably (Land, M. F., 1981). Once again we are left to conclude that *Deilephila*'s impressive visual performance can only be explained by spatial and temporal summation at higher levels in the visual system, a conclusion that future experimental work will no doubt verify.

2.05.7 Vision and Visual Behavior in Nocturnal Birds and Primates

Birds have excellent vision, with eyes that are considerably larger relative to body size than in most other animal groups (Walls, G. L., 1942; Martin, G. R.,

1994), an adaptation thought to be associated with rapid flight in bright environments. Diurnal birds that employ an active aerial visual hunting strategy, such as eagles, kites, hawks, and falcons, have even larger eyes for their body size than other birds (Brooke, M. *et al.*, 1999), which no doubt reflects their need for better spatial resolution. In birds, larger eyes are also accompanied by comparatively larger brains (Garamszegi, L. Z. *et al.*, 2002).

Even though most birds are diurnal, there are a considerable number of species that have become exclusively nocturnal (Martin, G. R., 1990). Many are flightless or nearly so and probably rely more on olfaction and mechanoreception, rather than on vision, for foraging. Well-known examples include the kiwis (*Apteryx* spp.), the night parrot, the ground parrot, and the kakapo, all endangered species from Australia or New Zealand. In contrast, actively flying species – including owls, frogmouths, nightjars, oilbirds, paurasques, the letter-winged kite, and various waterbirds – rely to a much greater degree on vision for orientation and feeding, and this is reflected in the size and design of their eyes. Like diurnal birds of prey, nocturnal flying birds generally have larger eyes for their body size than other birds (Brooke, M. *et al.*, 1999; Garamszegi, L. Z. *et al.*, 2002; Thomas, R. J. *et al.*, 2006; Hall, M. I. and Ross, C. F., 2007), an adaptation that has evolved in order to capture more light from a larger pupil (see Section 2.05.5.2), rather than to improve spatial resolution (a conclusion also drawn for the eyes of nocturnal primates: Kay, R. F. and Kirk, E. C., 2000; Kirk, E. C., 2004). Apart from their larger size, several other important adaptations have evolved within the eyes of nocturnal birds that enhance their sensitivity to light. Remarkably, one of these adaptations (found in the echolocating oilbird *Staetornis caripensis*) was, until very recently, known only from deep-sea fishes. For a fuller account of nocturnality in birds, the interested reader is referred to Martin's beautiful book on the subject (Martin, G. R., 1990).

In the discussion below, comparisons will also be made, where relevant, with nocturnal primates, another animal group whose members – lemurs, lorises, pottos, aye-ayes, bushbabies, tarsiers, and the owl monkey *Aotus* – have excellent nocturnal vision (for reasons similar to those we will outline below for birds).

2.05.7.1 Optical Adaptations for Increased Sensitivity

As we saw earlier, wider pupils, shorter relative focal lengths, and larger photoreceptors with wider receptive fields all improve photon capture N (eqn [3]) and increase sensitivity S (eqn [2]). These are common features of camera eyes in nocturnal vertebrates and are readily seen in the eyes of nocturnal birds (Hall, M. I. and Ross, C. F., 2007) and nocturnal primates (Kirk, E. C., 2004).

The camera eyes of nocturnal vertebrates are frequently constructed with a large, highly curved, and powerful cornea and a significantly thickened lens (especially in primates) that shortens the posterior nodal distance and shifts it closer to the retina than in a diurnal eye (Figure 10(c)). To achieve a focused image on the retina, this implies that the focal length f is relatively shorter in such an eye, and a shorter focal length leads to a lower F-number (see Section 2.05.6.1.1) and greater sensitivity (eqn [2]). As we discussed earlier, an eye of lower F-number (the ratio of focal length f to pupil diameter A) receives a brighter retinal image and is thus better adapted to vision in dim light. Indeed, a survey of F-numbers in nocturnal and diurnal birds and primates supports this principle: the eyes of nocturnal species have considerably lower F-number than those of diurnal species (Table 1; Pettigrew, J. D., 1982; Kirk, E. C., 2006).

The finite size of the vertebrate skull, and the demand for high sensitivity via a large pupil, has resulted in the evolution of very large eyes relative to head size in nocturnal animals (Walls, G. L., 1942; Brooke, M. *et al.*, 1999; Garamszegi, L. Z. *et al.*, 2002; Howland, H. C. *et al.*, 2004; Kirk, E. C., 2004; Thomas, R. J. *et al.*, 2006; Hall, M. I. and Ross, C. F., 2007). Nocturnal tarsiers and owl monkeys are excellent examples: in the latter, pupils can reach 2 cm in diameter. In tarsiers (Figure 10(a)), skillful hunters of nocturnal insects (Collins, C. E. *et al.*, 2005), the skull is dominated by enormous eye sockets (Figure 10(b)). Incredibly, each eye has a volume equal to that of the brain (Collins, C. E. *et al.*, 2005), and the eyes are believed to be the largest relative to body mass of any mammal (Polyak, S., 1957). Moreover, investigations of the brain reveal that the primary visual cortex (V1) of the tarsier *Tarsius spectrum* is unique among primates in that it occupies the largest proportion of the neocortex yet reported for this group (Collins, C. E. *et al.*, 2005). This finding no doubt reveals the importance of sensitive high-resolution vision for the tarsier's demanding predatory behavior and its locomotory habit of leaping from tree to tree.

Another common adaptation to life in dim light is an eye of tubular shape, and this is found in many nocturnal birds and deep-sea fishes (see Warrant, E. J. and Locket, N. A., 2004). The large forward-pointing eyes of owls are a good example (Figure 11a; Walls,

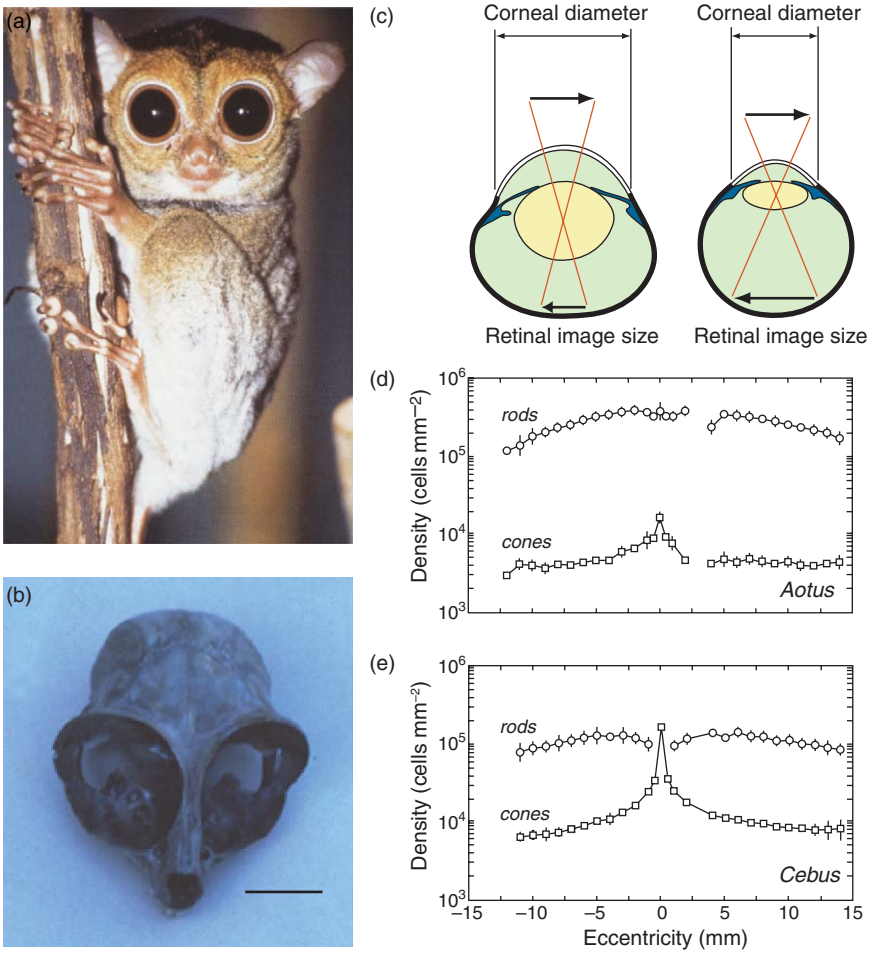

Figure 10 Nocturnal vision in primates. (a) The Western Tarsier *Tarsius bancanus*, whose huge eyes (each larger than its brain!) are likely to support excellent nocturnal vision. (b) The skull of a tarsier (*Tarsius* sp.), with huge eye sockets relative to head size. Scale bar = 10 mm. (c) A schematic comparison of eye morphology in the nocturnal bushbaby *Galago* (left) and the diurnal marmoset *Callithrix* (right). The larger corneal diameter of the bushbaby allows a larger pupil and greater sensitivity, while its thicker and more proximally placed lens shifts the posterior nodal point (roughly at the lens center) closer to the retina. This shortens the focal length, lowers the *F*-number, and increases sensitivity. It also leads to a smaller, and thus less well-resolved, image (as shown by the arrows). Redrawn with kind permission from Kirk E. C. (2004). (d and e) Photoreceptor densities as a function of retinal eccentricity in the nocturnal owl monkey *Aotus* (d) and the diurnal capuchin monkey *Cebus* (e). Note the larger rod density and lower cone density at all eccentricities in the owl monkey, and the great reduction of cones in its fovea. Nasal and temporal eccentricities are represented by positive and negative values, respectively (a) From Rowe, N. 1996. The Pictorial Guide to the Living Primates, Pogonias Press; used with kind permission of the photographer David Haring (Duke Lemur Center). (d, e) Adapted and redrawn with kind permission of Luiz Silveria from Yamada, E. S., Silveira, L. C. L., Perry, V. H., and Franco, E. C. S. 2001. M and P retinal ganglion cells of the owl monkey: morphology, size and photoreceptor convergence. Vision Res. 41, 119–131.

G. L., 1942; Martin, G. R., 1982; Murphy, C. J. *et al.*, 1985; Martin, G. R., 1994; Martin, G. R. and Katzir, G., 1999). A tubular form allows a portion of a larger (and thus more sensitive) spherical eye to fit onto a smaller head (Walls, G. L., 1942). This reduces the weight (payload) of the eye, and thus the energetic cost of maintaining visual function, while at the same time allowing a maximal pupil diameter (which improves sensitivity) and a comparatively longer focal length (which improves resolution). The price paid for this is a restricted visual field: the long tubular optics reduces the region of space from which light reaches the retina. In the tawny owl, the visual field of each eye has a width of 124°, about 40° less than in the more spherical eye of the European starling (Martin, G. R., 1984; 1986). Moreover, the more frontal placement of the owl's eyes (with a divergence angle of 55° that results in a binocular overlap of 48°) restricts the total field of vision to a frontal coverage of 200° width. In contrast, the

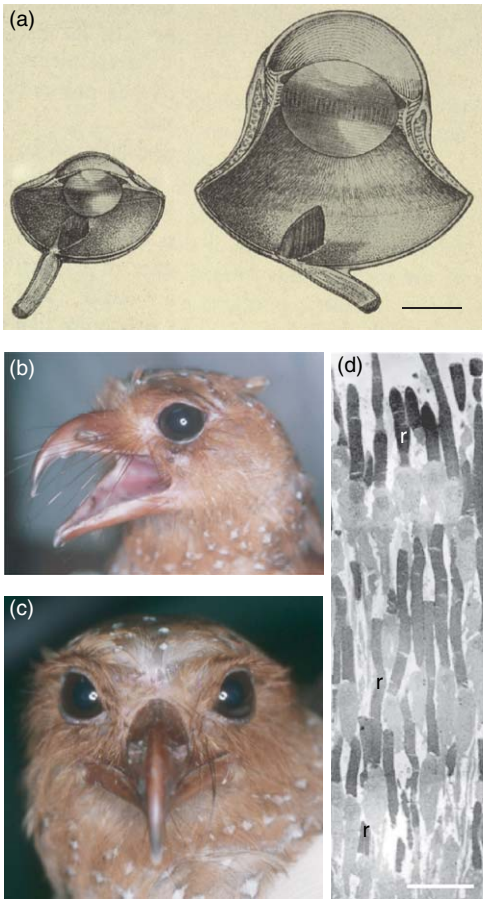

Figure 11 Nocturnal vision in birds. (a) Schematic cross-sections through the eyes of the diurnal swan *Cygnus olor* (left) and the nocturnal owl *Bubo bubo* (right). Note the large tubular form of the owl's eye and the more proximal position of the lens. Diagram adapted from Walls G. L. (1942). Side view (b) and frontal view (c) of the head of the oilbird *Steatornis caripensis*, showing the prominent eyes. Note the bird's rictal bristles in (b). (d) A section through the banked retina of the oilbird, showing the rod outer segments (*r*) arranged in three layers. Scales bar = 10 mm (a), 6 μm (d). (b–d) From Martin, G. R., Rojas, L. M., Ramirez, Y., and McNeil, R. 2004a. The eyes of oilbirds (*Steatornis caripensis*): pushing at the limits of sensitivity. Naturwissenschaften 91, 26–29, with the authors' kind permission.

starling, with more laterally placed eyes that diverge with an angle of 114°, has a total visual coverage of 328°. A binocular overlap similar to that of the owl can also be achieved by eye movements.

It should be stressed, however, that despite being common, large tubular eyes with narrow visual fields are not characteristic of nocturnal animals in general, including birds (Katzir, G. and Martin, G. R., 1998). For instance, the eyes of the nocturnal Caprimulgiformes, while being large relative to head size, are more conventionally shaped and placed laterally on the head. The oilbirds (Figures 11(b) and 11(c)) and common pauraques of South America are good examples (Martin, G. R. *et al.*, 2004a; 2004b), with narrow regions of frontal binocular overlap (25° and 38° wide, respectively) and a broad total visual coverage (around 270° in common pauraques). Despite having much smaller eyes than owls, these nocturnal birds still possess highly sensitive optics of low *F*-number (Table 1).

Because the eyes of nocturnal vertebrates are adapted to very low levels of light, their pupils tend to close very tightly during the day in order to protect the sensitive retina from overexposure to bright daylight. The vertical slit pupils of many nocturnal hunters, like the domestic cat, can almost completely close during the day (Walls, G. L., 1942; Ali, M. A. and Klyne, M. A., 1985). Interestingly, only one group of nocturnal birds – the skimmers – have a vertical slit pupil (Martin, G. R., 1990).

In addition to sensitive optics, many nocturnal animals also have a reflective layer within the retina, behind the photoreceptors – called the tapetum – that allows incident light to be reflected back through the retina. The tapetum thus allows a second chance for absorption of light that had not been absorbed during its first passage through the photoreceptors, thus effectively doubling the lengths of their outer segments. Despite this improvement in sensitivity, the unconstrained reflection provided by a flat tapetum can degrade spatial resolution (Walls, G. L., 1942; Munk, O., 1980; Nicol, J. A. C., 1989; Warrant, E. J. and McIntyre, P. D., 1991; Kirk, E. C. and Kay, R. F., 2004). This may be the reason why many nocturnal animals do not possess them: even though tapeta are common among the nocturnal Strepsirrhine primates (lemurs, lorises, bushbabies, pottos, and aye-ayes: Charles-Dominique, P., 1977), they are absent in the nocturnal Haplorhine primates (tarsiers and the owl monkey *Aotus*). Tapeta are also uncommon in the eyes of nocturnal birds, being found only in the eyes of some Caprimulgiformes, notably the nightjars (Nicol, J. A. C. and Arnott, H. J., 1974) and the common pauraque (Rojas, L. M. *et al.*, 2004).

2.05.7.2 Neural Adaptations for Increased Sensitivity

In the camera eyes of vertebrates, a common evolutionary response to a life in dim light has been a drastic change in the relative proportions of the rod and cone photoreceptors. The rods, responsible for

vertebrate vision in dim light, commonly dominate the retinae of both nocturnal and deep-sea vertebrates, and this is certainly the case for nocturnal birds and primates (Table 2). For instance, in the extreme case of the oilbird *S. caripensis*, there are 123 rods for every cone and one million rods per square millimeter (Martin, G. R. *et al.*, 2004a), the highest rod density recorded in any vertebrate and two-and-a-half times greater than the highest photoreceptor density recorded in a bird (380 000 cones mm^{-2} in the diurnal Brown Falcon *Falco berigora*; see Martin, G. R. *et al.*, 2004a). In other nocturnal birds, the ratio of rods to cones is much lower, but still high: in the barred owl *Strix varia* it is 10:1 and in the common pauraque *Nyctidromus albicolli* it is 5:1 (see Rojas, L. M. *et al.*, 2004; for other examples, see Table 2). In diurnal birds, the ratio is considerably lower, with the number of cones typically exceeding that of the rods: in the diurnal cattle egret *Bubulcus ibis*, the rod:cone ratio is 0.3:1 (Rojas, L. M. *et al.*, 1999a).

The same pattern can be found in primates (Figures 10(d) and 10(e); Table 2): at an eccentricity of 5 mm temporal of the fovea (−5 mm in Figures 10(d) and 10(e)), the density of rods in the nocturnal owl monkey *Aotus azarae* is about 60 times greater than the density of cones, while in the diurnal capuchin monkey *Cebus apella* the ratio is closer to 10:1 (Ogden, T. E., 1975; Wikler, K. C. and Rakic, P., 1990; Yamada, E. S. *et al.*, 2001; Silveira, L. C. L. *et al.*, 2001). Moreover, in *Cebus*, rods are absent altogether at the center of the fovea: instead, there is a massive peak in cone density, a characteristic of many diurnal vertebrates, including primates like ourselves. The situation is,

Table 2 Photoreceptor and convergence ratios in vertebrate eyes

Species	*Animal*	*Activity*	*Rods:cones*	*Rods:RGCs*	*Reference*

The ratio of rods to cones was calculated from linear transects of the retina in birds (and are averages for the entire retina), and from photoreceptor densities in primates (i.e., this ratio is thus not directly comparable between birds and primates). RGC, retinal ganglion cell; N, nocturnal; D, diurnal; C, crepuscular; P, parvocellular RGC; M, magnocellular RGC. Superscript letters: *a* = may be nocturnal and diurnal during the breeding season; *b* = nocturnal only in winter; *c* = central retina (eccentricity 0 mm); *d* = eccentricity 5 mm temporal of the fovea; *e* = eccentricity 5 mm from the fovea (averaged from the temporal, upper and lower quadrants of the retina, and calculated using equations given in reference 11). References to original articles are given in 1 (Rojas, L. M. *et al.*, 1999a), 2 (Rojas, L. M. *et al.*, 1999b), and 3 (Rojas, L. M. *et al.*, 2004). Other references: 4 = Rojas L. M. *et al*. (1993); 5 = Yamada E. S. *et al*. (1998); 6 = Dkhissi-Benyahya O. *et al*. (2001); 7 = Silveira L. C. L. *et al*. (1994); 8 = Lima S. M. A. *et al*. (1996); 9 = Yamada E. S. *et al*. (2001); 10 = Silveira L. C. L. *et al*. (2001); 11 = Silveira L. C. L. *et al*. (2004); 12 = Goodchild A. K. *et al*. (1996) (and references therein).

however, quite different in *Aotus*. The large peak in foveal cone density seen in *Cebus* is missing in *Aotus* – the rods, absent in the central fovea of *Cebus*, dominate the fovea of *Aotus* (Figures 10(d) and 10(e)). Part of the reason for the great reduction of cones in the owl monkey *Aotus* is that it has lost two of the three classes of cones typical of diurnal primates like *Cebus*, or ourselves (Wikler, K. C. and Rakic, P., 1990). These three cone classes – short (S), medium (M), and long (L) wavelength sensitive – are responsible for the well-developed trichromatic color vision found in most diurnal Haplorhine primates. *Aotus* has lost its S-cone due to a defect in the S-class opsin gene (Wikler, K. C. and Rakic, P., 1990; Jacobs, G. H. *et al*., 1993; 1996), and the single remaining class is an M/L-cone with absorption peak at 543 nm. Loss of the S-cone has also occurred in the thick-tailed bushbaby *Otolemur crassicaudatus* (Deegan, J. F. and Jacobs, G. H., 1996; Jacobs, G. H. *et al*., 1996), implying that owl monkeys and bushbabies are monochromats. The nocturnal mouse lemur *Microcebus murinus* is similar to the owl monkey and bushbaby, although the S-cone is present, but in exceptionally low numbers (Dkhissi-Benyahya, O. *et al*., 2001). Although it is probable that owl monkeys, bushbabies, and possibly nocturnal lemurs have sacrificed color vision to achieve higher sensitivity, this does not imply that nocturnal color vision in other species is impossible. Indeed, as we saw above, it has recently been discovered in hawkmoths (Kelber, A. *et al*., 2002) and now also in nocturnal geckoes (Roth, L. S. V. and Kelber, A., 2004). And interestingly, it has been shown that tarsiers, unlike owl monkeys and bushbabies, have retained their S-cones (Hendrickson, A. *et al*., 2000), which even opens the possibility for dichromatic nocturnal color vision in a primate.

In oilbirds, the enormous rod:cone ratio (123:1) is due to a remarkable retinal adaptation, previously described only in deep-sea fishes (Warrant E. J. and Locket, N. A., 2004). As in deep-sea fishes, the rods of the oilbird are arranged in layers, one above the other, to create a so-called banked retina (Figure 11(d); Martin, G. R. *et al*., 2004a). In oilbirds, there are three such layers and their role is to increase the pathlength of light traveling through the retina, thus maximizing photon absorption. As a comparison, in the deep temporal foveae of the alepocephalid deep-sea fish *Bajacalifornia drakei*, there are no less than 28 layers of rod outer segments through which the incoming light must pass, although it is still unclear whether all layers are functional (Locket, N. A., 1985). Even though it remains unresolved as to whether banked retinae compromise spatial resolution, the increased sensitivity they undoubtedly afford represents a remarkable example of convergent evolution.

As we mentioned earlier, the photoreceptors of arthropods are capable of responding to single photons of light (see Section 2.05.6.2.1), and this is also the case for vertebrate rods (e.g., Baylor, D. A. *et al*., 1980; Rieke, F. and Baylor, D. A., 1998). Despite this apparent sensitivity, signal reliability in vertebrate photoreceptors – just as in invertebrate photoreceptors – is compromised in dim light due to various sources of noise (Donner, K., 1992), both intrinsic (dark noise and transducer noise) and extrinsic (photon shot noise). Capturing more light can lessen the deleterious effects of this noise, and as we have seen above, the optical structures of nocturnal eyes are adapted to do this. Neurally, however, just as in arthropods, there is no evidence that the rods of nocturnal vertebrates are intrinsically better at capturing and absorbing light than those of diurnal vertebrates. This can be seen in birds: the absorption coefficient of rods in the tawny owl is $0.039\,\mu m^{-1}$ (Bowmaker, J. K. and Martin, G. R., 1978), a value actually less than that found in diurnal chickens ($0.053\,\mu m^{-1}$: Bowmaker, J. K. and Knowles, A., 1977) and pigeons ($0.049\,\mu m^{-1}$: Bowmaker, J. K., 1977). There is, however, evidence that the rod-dominated retinae of some nocturnal birds respond more slowly (Rojas, L. M. *et al*., 1997; 1999a), and more sensitively, to stimulation with light than the cone-dominated retinae of diurnal birds. Measurements of the scotopic (dark-adapted, rod-mediated) electroretinogram (ERG) – and specifically the amplitude of the b-wave – suggest that in some groups of birds, the rods of nocturnal species are more sensitive to light than those of diurnal species (Rojas, L. M. *et al*., 1997; 1999a; 2004). However, in wading birds, this does not seem to be the case (Rojas, L. M. *et al*., 1999b).

Perhaps the greatest neural determinant of light capture, resolution, and sensitivity in a vertebrate camera eye is the extent of convergence (or summation), via the bipolar cells, of photoreceptor signals onto the underlying ganglion cells. In all vertebrate retinae, photoreceptors typically converge in large numbers onto single ganglion cells, the exact convergence ratio depending on the distance (eccentricity) from the center of the retina. The convergence ratio is lowest at the exact center of the retina. In the central foveae of diurnal anthropoid primates, signals

from a single cone photoreceptor are divided between two midget (parvocellular) ganglion cells, one OFF type and one ON type (Wässle, H. and Boycott, B., 1991). As one moves in any direction away from the fovea, the convergence ratio increases and, in the periphery of the retina, can become very great indeed, with large numbers of photoreceptor signals converging onto single ganglion cells.

The size of the converging photoreceptor pool, together with noise removal mechanisms in the photoreceptor–bipolar cell synapse (van Rossum, M. C. W. and Smith, R. G., 1998), sets the potential sensitivity of the receiving ganglion cell and the local spatial resolution (Hughes, A., 1977; Collin, S. P., 1999). A smaller photoreceptor pool builds a smaller and less-sensitive ganglion cell receptive field, and the density profile of ganglion cells across a retina reveals the trade-off between spatial resolution on the one hand and sensitivity to an extended source on the other. A denser packing of ganglion cells indicates a region of higher resolution where sensitivity has been sacrificed. For instance, in the central foveae of diurnal anthropoid primates, one cone supplies two ganglion cells, and the density of cones thus sets the local anatomical spatial resolution (which is also the highest achievable in the eye). As one moves away from the fovea, photoreceptor summation leads to a lower density of ganglion cells and lower spatial resolution, but higher sensitivity. Thus, one may expect vertebrates active in dim light to have a higher convergence ratio of photoreceptors (i.e., rods) to ganglion cells than found in diurnal vertebrates, and this is certainly the case (Hughes, A., 1977), even in the very center of the retina (Kirk, E. C. and Kay, R. F., 2004). The nocturnal domestic cat, for instance, has a higher convergence ratio and coarser vision than a human but are much more sensitive to light (Pasternak, T. and Merigan, W. H., 1981). The same can be said of nocturnal primates (Table 2): in the nocturnal owl monkey *Aotus*, the convergence ratios of rods to magnocellular and parvocellular ganglion cells at an eccentricity of −5 mm (Figures 10(d) and 10(e)) are around six to seven times greater than in the diurnal capuchin monkey *Cebus* (Silveira, L. C. L. *et al.*, 1994; Lima, S. M. A. *et al.*, 1996; Silveira, L. C. L. *et al.*, 2001; Yamada, E. S. *et al.*, 2001; Silveira, L. C. L. *et al.*, 2004). This is due to a significantly larger rod density (Figures 10(d) and 10(e)) and a much greater dendritic field size (and thus lower density) of bipolar cells (Dos Santos, S. N. *et al.*, 2005) and ganglion cells in *Aotus*. In fact, the magnocellular and parvocellular ganglion cells of *Aotus* have receptive field areas that are about four and six times larger (respectively) than those of *Cebus*, and this results in three times fewer ganglion cells (in total) within the eye. The largest area of difference is in the central (foveal) part of the retina, which in *Aotus* has fewer than 35% of the cones and fewer than 20% of the ganglion cells that are found centrally in *Cebus* (Silveira, L. C. L. *et al.*, 2004). However, despite having fewer ganglion cells, *Aotus* has a higher proportion of magnocellular cells than found in *Cebus*. This is commensurate with the presumed role of the magnocellular pathway, which is to mediate pattern vision at scotopic light levels (Yamada, E. S. *et al.*, 2001). Thus, the higher convergence ratios found in *Aotus* compared to *Cebus*, together with monochromacy, low ganglion cell densities (especially centrally), and a bias toward magnocellular processing, all suggest that the retinae of owl monkeys are adapted for coarser but more sensitive vision at very low light levels. This conclusion is reinforced by the structure of the lateral geniculate nucleus (LGN), the first relay station for information traveling from the eye to the visual cortex. In diurnal Haplorhine primates like ourselves, the LGN is divided into four large dorsal parvocellular layers (receiving inputs from the large proportion of parvocellular ganglion cells) and two smaller ventral magnocellular layers (receiving inputs from magnocellular ganglion cells). This dominance of the parvocellular division of the LGN in diurnal Haplorhine primates reflects their need for highly resolved foveal vision and color analysis during the day. In contrast, owl monkeys, tarsiers, and nocturnal Strepsirrhine primates (lorises, lemurs, and bushbabies) have only two parvocellular layers, which no doubt reflects their considerably less foveate retina and lack of color vision (Collins, C. E. *et al.*, 2005).

The same adaptational patterns are probably also found in nocturnal birds, but to my knowledge, no proper measurements have been made of convergence ratios and ganglion cell densities in this group.

2.05.7.3 Visual Behavior in Nocturnal Birds and Primates

2.05.7.3.1 Vision versus other senses at night

As mentioned above, some nocturnal birds are flightless, foraging for food on the forest floor (e.g., kiwis). Others are active flyers, frequently taking prey on the wing (e.g., owls). This difference in the lifestyles of birds has had a profound influence on the evolution

not only of their visual systems but also of their other sensory systems. The same is true of nocturnal primates: some groups (e.g., lorises) are slowly moving and capture slowly moving prey, while others (e.g., bushbabies and tarsiers) rapidly leap from tree to tree and capture fast-moving, and often flying, prey.

Since flightless foraging nocturnal birds potentially have less demanding visual requirements than their flying relatives, one might expect the energetic demands associated with extracting adequate visual information in dim light (Laughlin, S. B. *et al.*, 1998; Laughlin, S. B., 2001) to drive the evolution of regressed visual systems in these birds (Martin, G. R. *et al.*, 2007). In that case, other senses, such as olfaction and mechanoreception, could then take over the role of guiding the animal. This has indeed been a common evolutionary outcome in flightless nocturnal birds, the kiwis providing an excellent example. These birds have very small eyes relative to body mass (Brooke, M. *et al.*, 1999), with the smallest visual fields known for any bird and an optic tectum that is markedly reduced (Martin, G. R. *et al.*, 2007). In contrast, the olfactory and tactile senses of kiwis are greatly enhanced, with the long bill acting as a highly sensitive probe that the bird uses to search the leaf litter for food. The bill tip is covered in highly unusual mechanosensory pits, and in addition, two large nostrils open laterally at the same location (Martin, G. R. *et al.*, 2007). This nostril location is also very unusual for birds – most bird nostrils are located at the base of the bill. Information from this remarkable olfactory-tactile probe is processed within enlarged regions of the brain that are specialized for these sensory modalities (Martin, G. R. *et al.*, 2007). Many waterbirds, while wandering the mudflats and probing for submerged prey at night, also rely exclusively on tactile information collected by the bill, despite being visual feeders during the day (Robert, M. and McNeil, R., 1989; McNeil, R. *et al.*, 1992; 1993).

Even for actively flying nocturnal birds, the difficulties associated with seeing at night have not only resulted in enhanced visual sensitivity, but also in enhanced hearing (e.g., owls), olfaction (e.g., oilbirds), and touch (e.g., frogmouths). The oilbirds are especially interesting. Not only do these cave-dwelling birds apparently have enhanced olfactory abilities (Snow, D. W., 1961; Bang, B. G. and Wenzel, B. M., 1985; Martin, G. R., 1990), they also use echolocation to find their way around within the pitch-dark cave interior (see Martin, G. R., 1990). However, this echolocation is switched off upon leaving the cave at night, after which point vision and olfaction take over. Moreover, the oilbirds, like many nocturnal Caprimulgiformes, have long rictal bristles that project from the base of the beak (Figure 11(b)). These bristles are assumed to aid in the detection of food, for instance by bending when they come into contact with prey, thus providing a mechanosensory cue for guiding the beak, and triggering a peck.

Very similar conclusions can also be made for the nocturnal primates. After years of careful field studies in Gabon, Pierre Charles-Dominique P. (1977) provided our first and clearest picture of nocturnal behavior in African lorisines (the potto *Perodicticus potto* and Angwantibo *Arctocebus calabarensis*) and galagines (six species of bushbabies). His meticulous documentation of the feeding habits, locomotion, and social interactions of these nocturnal primates allowed him to assess the importance of vision, and the other senses, in their behavior. The lorisines slowly climb trees and traverse branches in the forest canopy and rely heavily on olfaction for capturing slow or sedentary insect prey. This is particularly true of the Angwantibo, which apparently sees rather poorly. The potto, whilst having better vision, also relies heavily on olfaction for capturing insect prey (Charles-Dominique, P., 1977). In contrast, bushbabies (just like tarsiers: Castenholz, A., 1984; Collins, C. E. *et al.*, 2005) are much more visually driven and rely on this sense to accurately leap from tree to tree in the dark and to locate and manipulate insect and vertebrate prey. Auditory localization of prey is also important (Charles-Dominique, P., 1977). Olfaction, whilst certainly useful, is of less importance in prey capture. Moreover, even though some nocturnal primates possibly use scent to mark preferred travel routes in the forest canopy, and to recognize conspecifics, it again seems that vision is the most important sense for selecting routes (Charles-Dominique, P., 1977; Wright, P. C., 1989) and possibly even for recognizing other members of the group (e.g., facial feature recognition in the owl monkey: Bearder, S. K. *et al.*, 2006).

Thus, despite having large and sensitive eyes, flying nocturnal birds and leaping nocturnal primates rely on all of their senses to survive. Nevertheless, considerable information is gained visually, and much of their behavior is visually driven. How well do nocturnal birds and primates actually see?

2.05.7.3.2 Visual performance in dim light

Whilst many anecdotal field observations exist attesting to the visual prowess of nocturnal birds

(especially owls) and primates, exceedingly few studies have been made to behaviorally measure visual performance in dim light quantitatively.

Apart from a few inconclusive earlier studies (Hecht, S. and Pirenne, M. H., 1940; Dice, D. L., 1945; Lindblad, J., 1967), Fite K. V. (1973) and Martin and colleagues (Martin, G. R. and Gordon, I. E., 1974a; 1974b; Martin, G. R., 1974, 1977) were the first and, to my knowledge, only investigators that have reliably measured dim-light visual performance in nocturnal birds (contrast sensitivity has been measured in barn owls, but not at scotopic light levels: Ghim, M. M. and Hodos, W., 2006). Behavioral methods, based on training birds to associate food with a visual stimulus, were used to measure absolute sensitivity in the tawny owl (Martin, G. R., 1977) and scotopic visual acuity in the great horned owl (Fite, K. V., 1973). Their results reveal that these owls, despite their nocturnal habits and large eyes, have only 2.2 times greater absolute sensitivity and four times greater threshold visual acuity (Figure 12) than humans.

These small differences in performance between owls and humans are probably explained on the basis of differences in the optics and sizes of their eyes

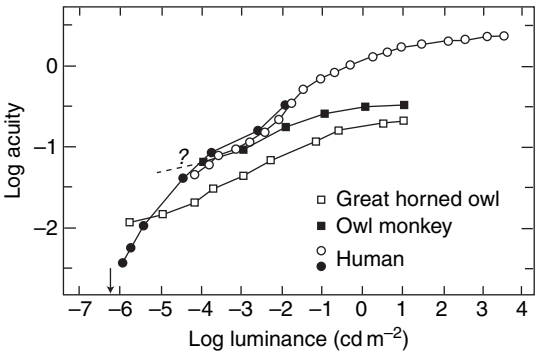

Figure 12 Visual acuity in nocturnal vertebrates. The visual acuity of the human (circles), the great horned owl *Bubo virginianus* (open squares), and the owl monkey *Aotus trivirgatus* (filled squares) as a function of luminance. At each intensity, acuity is calculated from the minimum angular width w (in minutes of arc) of a stripe, from a uniform black-and-white square-wave grating, that is just visible to the observer. Acuity $= \log w^{-1}$. The arrow marks the absolute visual threshold of the tawny owl (see Figure 2). Adapted and redrawn with kind permission from Martin G. R. (1990), with data for the owl monkey taken from Jacobs G. H. (1977b). Jacobs G. H. (1977b) also published acuity data for humans that indicate slightly poorer performance at the dimmest light levels than the human data presented here (by about 0.3 log units of acuity) – his owl monkeys outperformed his human observers at 10^{-4} cd m^{-2} and could presumably continue to so even at dimmer intensities (dashed line).

(Martin, G. R., 1990). Humans and tawny owls have eyes of similar axial length (25 and 28.5 mm, respectively), but the owl has a significantly larger pupil (13.3 vs. 8 mm, fully dark adapted). This endows the tawny owl with a lower F-number (1.3 vs. 2.13: Table 1), and thereby a retinal image that is $(2.13/1.3)^2 = 2.7$ times brighter than in humans, an improvement in optical sensitivity entirely consistent with the 2.2 times greater absolute sensitivity measured behaviorally. The greater acuity of the great horned owl is certainly partly due to its more sensitive eyes (also of much lower F-number than the human eye: Table 1). However, the owl's much larger axial eye length (38.7 mm), and correspondingly longer focal length, must also play a part. The difference in axial eye length suggests that an object imaged on the owl's retina would be about 1.5 times larger than the image formed on a human retina. Moreover, the deep convexiclivate foveal pit of the great horned owl (Fite, K. V., 1973) may also have telephoto properties that magnify the image in the retina, thereby improving acuity further (as is known for diurnal birds of prey: Snyder, A. W. and Miller, W. H., 1978).

To my knowledge, absolute sensitivity has never been measured behaviorally in a nocturnal primate (although spectral thresholds, which are not the same thing, have been measured in the owl monkey *Aotus trivirgatus*: Jacobs, G. H., 1977a). However, acuity measurements have been made, and these are comparable to those made in the great horned owl. In the owl monkey, visual acuity is higher than that in the great horned owl at all intensities (Jacobs, G. H., 1977b) and even exceeds that of humans at the lowest intensities (Figure 12), suggesting that compared to many nocturnal vertebrates, *Aotus* probably has excellent night vision. Spatial resolution has also been measured in the bushbaby *Galago crassicaudatus*, but not at scotopic light levels (Langston, A. *et al.*, 1986).

What do the above measures of absolute sensitivity and threshold visual acuity in nocturnal birds and primates tell us about their visual abilities relative to other animals? First, examination of Figure 2 reveals that the absolute sensitivity of the tawny owl would allow it to see without difficulty under all levels of natural nocturnal illumination in open habitats, but in closed habitats (like woodland) it would be facing difficulties, particularly on overcast nights. The situation is slighter better for the nocturnal domestic cat, and slightly worse for humans. Diurnal pigeons, with their small and insensitive eyes, would be

unable to see well in all but the brightest nocturnal habitats. Second, at threshold, and at a distance of 1 m, the acuity of the great horned owl would prevent it seeing high-contrast objects smaller than about 3 cm in diameter (Martin, G. R., 1990). At a viewing distance of 10 m, the minimum visible size would be 29 cm! For the much lower contrasts of objects found in natural habitats (Laughlin, S. B., 1981b; Vu, T. Q. *et al.*, 1997), these minimum sizes would be considerably larger.

These results suggest that the retinas of owls and humans are equally sensitive and that the modest enhancements in visual performance found in owls are due to optical differences alone. This conclusion at first seems surprising. Humans are considered diurnal animals with poor night vision, whilst owls are thought to be quintessential nocturnal hunters. Indeed, many species of owls fly in cluttered woodland environments at night when light levels are extremely low (Figure 2), even capturing their prey on the forest floor from the air. How can the above measurements of visual performance be reconciled with these observations? The answer lies in an examination of their predation strategies in the wild.

2.05.7.3.3 Visually guided prey capture, locomotion, and navigation

As we saw in Figure 2, nocturnal light levels can vary over many orders of magnitude, being brightest in open habitats with cloudless, moonlit skies and dimmest under a forest canopy illuminated by a moonless but overcast sky. As we mentioned above, even a diurnal pigeon is probably able to see reasonably well on the brightest nights, so it is not surprising that many nocturnal birds and primates, adapted for vision in dim light, are able to do so as well. But seeing well enough to visually capture prey, or to move through the forest, may restrict some nocturnal animals to the brighter nocturnal light levels, thus restricting the types of habitats where these animals can live. It may also restrict the range of methods they can adopt for locomotion or to capture prey. Those animals that live in the dimmest nocturnal habitats may be forced to give up on vision altogether and rely on other senses. As we will see, all these scenarios have evolved among nocturnal birds (Martin, G. R., 1990) and primates (Wright, P. C., 1978; Bearder, S. K. *et al.*, 2006).

Because the world under a closed forest canopy is about 100 times dimmer than an open field or an intertidal mudflat (Figure 2), it is not surprising to find that many nocturnal birds, due to insufficient sensitivity, are restricted to hunt prey visually in open habitats. All of the nocturnal Charadriiformes – particularly the coursers, stone-curlews, and thick-knees – inhabit open habitats with sparse and/or short vegetation in the vicinity of water, with good visibility and no barriers to walking and running, their chief locomotory method for detection and pursuit of prey (Martin, G. R., 1990). Despite their large eyes, hearing no doubt plays an important role in their detection of prey (mostly larger insects and other invertebrates). Among the Caprimulgiformes, nightjars (Martin, G. R., 1990) and pauraques (Martin, G. R. *et al.*, 2004b) also restrict hunting to open habitats, or above the forest canopy. Unlike coursers, stone-curlews, and thick-knees, the nightjars and pauraques hunt prey on the wing, taking insects from the air. The nightjars do this by trawling the air ahead for insects, in much the same way that a whale trawls for plankton. They achieve this with an extraordinarily large gape, a gape that is afforded by specialized skull adaptations that allow the beak to open to a much greater extent than in other birds (Buhler, P., 1970). The nightjar beak is also richly endowed with rictal bristles, suggesting that tactile cues may also alert the bird to collisions with insects (thereby triggering prey capture behavior). A wide gape and rictal bristles are also characteristics of the common pauraque (Martin, G. R. *et al.*, 2004b). Thus, in nightjars and pauraques, even though vision is probably important for flight orientation, it may play a lesser role in prey capture. Nevertheless, both birds have large eyes, and both are known to take insects from below, indicating that, silhouetted against the night sky, a large flying insect may be a reliable visual target (Martin, G. R. *et al.*, 2004b). Many Strigiformes (owls) are also open-habitat hunters. Good examples include the snowy owl, the short-eared owl, and the African marsh owl (Martin, G. R., 1990). These owls prefer open country devoid of trees, tend to be nonsedentary, and are active in brighter light levels, typically hunting during the day or in twilight. They hunt by visually scanning the landscape for potential prey from an elevated vantage point (or perch), a strategy that probably requires the higher light levels found in open crepuscular habitats.

In contrast to life in an open habitat, life under the closed canopy of a forest is particularly challenging for nocturnal animals that use vision for locomotion and prey capture. As we mentioned above, many nocturnal primates (such as the potto *Perodicticus potto* and the Angwantibo *Arctocebus calabarensis*) reduce

their dependence on vision by moving very slowly and relying on other senses, such as olfaction and hearing, for capturing prey (Charles-Dominique, P., 1977). However, others clearly have excellent nocturnal vision. Tarsiers and bushbabies move through the dark nocturnal forest by deftly leaping from tree to tree and, like owl monkeys, follow familiar routes, suggesting the visual recognition of learned landmarks (Charles-Dominique, P., 1977; Wright, P. C., 1978). Moreover, vision plays an important role in prey capture (Charles-Dominique, P., 1977; Castenholz, A., 1984). Interestingly, however, many nocturnal primates reveal activity levels that are correlated to moonlight levels. The nightly wanderings of owl monkeys, lemurs, and bushbabies through the forest canopy are longer for more intense levels of moonlight. On moonless nights, these animals move very little at all. However, this reduction in travel distance on the darkest nights is more likely due to predation risk rather than to limitations in visual sensitivity (Wright, P. C., 1978; Donati, G. *et al.*, 2001; Bearder, S. K. *et al.*, 2006).

The difficulties of living and hunting under a dark forest canopy are similar for nocturnal birds, especially if hunting also involves flight. Frogmouths and potoos (Caprimulgiform birds) and various species of owls (Strigiform birds) fall into this category. Most pounce on prey (typically invertebrates and small rodents) from an elevated perch, and many are sedentary and solitary in their habits. And all need to deal with life in the forest understory, which is not only very dim, but also spatially complex, with many obstacles to flight and orientation. Like the nightjar, the tawny frogmouth *Podargus strigoides* has a wide gape and a beak surrounded by rictal bristles and takes prey by pouncing upon them from an elevated perch or by chasing them along the ground (Martin, G. R., 1990). Despite its large eyes, it is not known what role (if any) vision plays in this behavior. Hearing may also be important, and the presence of rictal bristles also suggests a role for mechanoreception.

Not all owls that frequent forests also hunt there (Martin, G. R., 1990). Many species only roost in the forest but restrict their hunting to open areas away from forests where light levels are higher. Good diurnal–crepuscular examples include the great gray owl, the hawk owl, and the pygmy owl, while nocturnal-crepuscular examples include the long-eared owl, Tengmalm's owl, the eagle owl, and the barn owl (Martin, G. R., 1990). There are, however, a number of strictly nocturnal species that not only roost in the forest, but like frogmouths and potoos, also hunt there. These include the tawny owl, the ural owl, the barred owl, and the spotted owl, all perch-and-swoop hunters in the dark understory. As we discussed above, these owls must perform this hunting behavior in light levels at or below the minimum they can detect (Figure 2). How do they manage then to fly and capture prey in the forest at night? Part of the answer lies in their exquisite hearing: many owls, notably the long-eared owl, the barn owl, and the barred owl, are capable of locating and capturing prey in total darkness, guided only by the sounds of the prey as it moves through the leaf litter (Payne, R. S. and Drury, W. H., 1958; Payne, R. S., 1962; 1971). In other words, owls are capable of flying blind and herein lies the key to how they cope with the dark nocturnal forest habitat. To be able to fly blind, owls must know their surroundings intimately, otherwise crashes with trees (and injuries) would be inevitable. This would require owls to spend long periods in the same habitat, learning the locations of trees and other obstacles. Not surprisingly then, it turns out that the more strictly nocturnal species of owls are also those species which are most territorial and most sedentary (Martin, G. R., 1990). The tawny owl, the ural owl, the barred owl, and the spotted owl – the most strictly nocturnal forest dwellers – all have small territories that are vigorously defended, and they never leave these territories throughout their entire lives. Tawny owls can have territories as small as 16 Ha, depending on this territory for all prey that it eats throughout its life (which may be up to 5 years: Martin, G. R., 1990). To capture this prey, it is very likely that these owls learn the spatial layout of trees and bushes within their territories, allowing them to fly blind for short distances through the forest after hearing their prey. Their eyes may be sensitive enough to detect coarser high-contrast details in their habitat that aid longer flights within the territory (such as gaps in the forest canopy), but it is probably the spatial memory of local obstacles within the territory that ultimately guides nocturnal flight (Martin, G. R., 1990). Such a phenomenal memory task, while overwhelming for humans, is not unknown for birds – many species have remarkable memory (see MacPhail E. M., 1986, for a review). However, developing a spatial memory such as this requires that the owl remains within its territory, and this is precisely what it does. However, whether such a strategy explains the unusual nocturnal hunting prowess of owls remains to be demonstrated.

2.05.8 Conclusions

The colors and contrasts of the nocturnal world are just as rich as those found in the diurnal world, and many animals – both vertebrates and invertebrates – have evolved visual systems to exploit this abundant information. Via a combination of highly sensitive optical eye designs, and unique alterations in the morphology, circuitry, and physiology of the retina and higher visual centers, nocturnal animals are capable of advanced and reliable vision at night. They can see color and negotiate dimly illuminated obstacles while flying or leaping through the forest understory. They can also navigate using learned terrestrial landmarks, the constellations of stars, or the dim pattern of polarized light formed around the moon. Nevertheless, the enormous span of intensities found at night forces many animals to restrict their visual activities to brighter nocturnal light levels, such as those experienced in an open and/or moonlit habitat. However, many other nocturnal animals – such as owls, bushbabies, and tarsiers – are active in the very dimmest habitats, flying, leaping, and capturing prey in extremely little light. Many owls, it seems, have dispensed with vision altogether, relying on hearing and a small and well-known territory to fly blind through the forest in pursuit of prey. But tarsiers, bushbabies, and owl monkeys, even on the darkest nights, apparently rely on vision to execute the daily tasks of life. Exactly how well they see is still an open question, and a fascinating and fruitful avenue for future research.

Acknowledgments

I wish to thank Dan-Eric Nilsson, Almut Kelber, Graham Martin, Chris Kirk, David Haring, and Luiz Silveira for graciously allowing me to reproduce their figures in this review. I am also extremely grateful for the ongoing support of the Swedish Research Council (Vetenskapsrådet) and the Royal Physiographic Society of Lund.

Glossary

achromatic Perceptually, devoid of hue or colorless. The nonchromatic dimension of a visual stimulus; including neutral grays, white, and black.

anomalous trichromacy A type of color blindness, in which one of the three cone pigments is altered in its spectral sensitivity, but trichromacy is not fully impaired.

chromatic Perceived as having hue or being colored (blue, green, yellow, red, purple, etc.). The hue and saturation dimensions of a visual stimulus.

color match A perceptual match between pairs or mixtures of lights with different spectral power distributions (which are therefore metamers).

color matching function (CMF) $\bar{x}(\lambda), \bar{y}(\lambda)$, and $\bar{z}(\lambda)$. Tristimulus values, usually defined for an equal-energy spectrum locus.

Commission Internationale de l'Éclairage (CIE; or International Commission on Illumination) An organization that recommends international standards of color and lighting.

cone fundamentals Cone spectral sensitivities: $\bar{l}(\lambda), \bar{m}(\lambda),$ and $\bar{s}(\lambda)$ in color matching function (CMF) notation. These are the CMFs that would result if imaginary primaries could be used that uniquely stimulated the three cones.

dichromacy A type of color blindness in which one of the three normal cone pigments is missing and color vision is reduced to two dimensions, so that any test light can be matched with a mixture of only two independent primary lights. There are three kinds of dichromacy: protanopia (lacking the L-cones), deuteranopia (lacking the M-cones), and tritanopia (lacking the S-cones).

large-field or 10-deg matches Color matches for centrally viewed, circular fields subtending 10-deg diameter of visual angle.

mesopic Light levels at which both rods and cones operate.

monochromacy A type of color blindness, in which two or all three of the cone pigments are

missing and color and lightness vision is reduced to a single dimension, so that any test light can be matched with a single primary light. At night, when only the rods are functioning, normal observers are monochromats.

photometry The measurement and quantification of the luminous efficiency of lights. It is intended to be independent of color.

photopic Light levels at which only cones operate.

photopic luminous efficiency function Photometric measure of the efficiency or effectiveness as a function of wavelength under photopic, rod-free conditions: $V(\lambda)$ or $\bar{y}(\lambda)$.

photoreceptors The light-sensitive receptors, lying on the rear surface of the eye or retina, which transduce photons into electrical signals. Morphologically and physiologically, they can be distinguished as either rods, responsible for our achromatic night vision, or cones, responsible for our chromatic daytime vision.

primary lights R, G, B. The three independent primaries (real or imaginary) to which the test light is matched (actually or hypothetically), when defining color-matching functions. They must be independent in the sense that no combination of any two can match the third.

scotopic Light levels at which only rods operate.

small-field or 2-deg matches Color matches for centrally viewed, circular fields subtending 2-deg diameter of visual angle.

trichromacy The ability of normal observers to match test lights with a mixture of three independent primary lights, one of which may have to be added to the test light to complete the match.

tristimulus values *R*, *G*, *B*, the amounts of the three primaries required to match a given stimulus.

univariance The output of a photoreceptor varies unidimensionally according only to the rate of photon absorption.

visual angle The angle subtended by an object in the external field at the effective optical center of the eye: $\theta = 2\tan^{-1}([x/2]/d)$ where x is the dimension of the object that is of interest (e.g., height, width, or diameter) and d is the distance of the object from the eye.

2.06.1 Introduction

Vision is initially limited by the transduction properties of the light-sensitive photoreceptors in the eye, and in particular by their spectral sensitivities. In most observers with normal color vision, there are four photoreceptor classes: three types of cone photoreceptors, which are referred to as long-, middle-, and short-wavelength-sensitive (L, M, and S), according to the part of the visible spectrum in which they are most sensitive, and a single type of rod photoreceptor. A knowledge of the spectral sensitivities of these photoreceptors is essential for the understanding and modeling of visual function. Rods, which are more sensitive than cones, mediate vision at night when photons are relatively scarce, whereas cones mediate color vision during the day when photons are abundant. Those conditions under which the rods and the cones operate alone are known as scotopic and photopic, respectively, while those under which they operate jointly are known as mesopic (see Figure 1).

2.06.1.1 Univariance and Trichromacy

Photoreceptors are essentially sophisticated photon counters, the outputs of which vary according to the number of photons that they absorb (e.g., Stiles, W. S., 1948; Mitchell, D. E. and Rushton, W. A. H., 1971). Although the probability that a photon is absorbed by a photoreceptor varies substantially with wavelength (defining its spectral sensitivity), the effect of an absorbed photon is independent of wavelength. Thus, it is impossible to tell whether a change in the output of a single photoreceptor is due to a change in light intensity, or due to a change in wavelength. Color and intensity are confounded, so that the output of an individual photoreceptor is effectively color blind or monochromatic. By extension, normal photopic human vision, which depends on the outputs of three different classes of photoreceptor, is a trichromatic or trivariant system. A behavioral consequence of trichromacy is that observers can match a test light of any spectral composition to a mixture of just three primary lights, as illustrated in Figure 2.

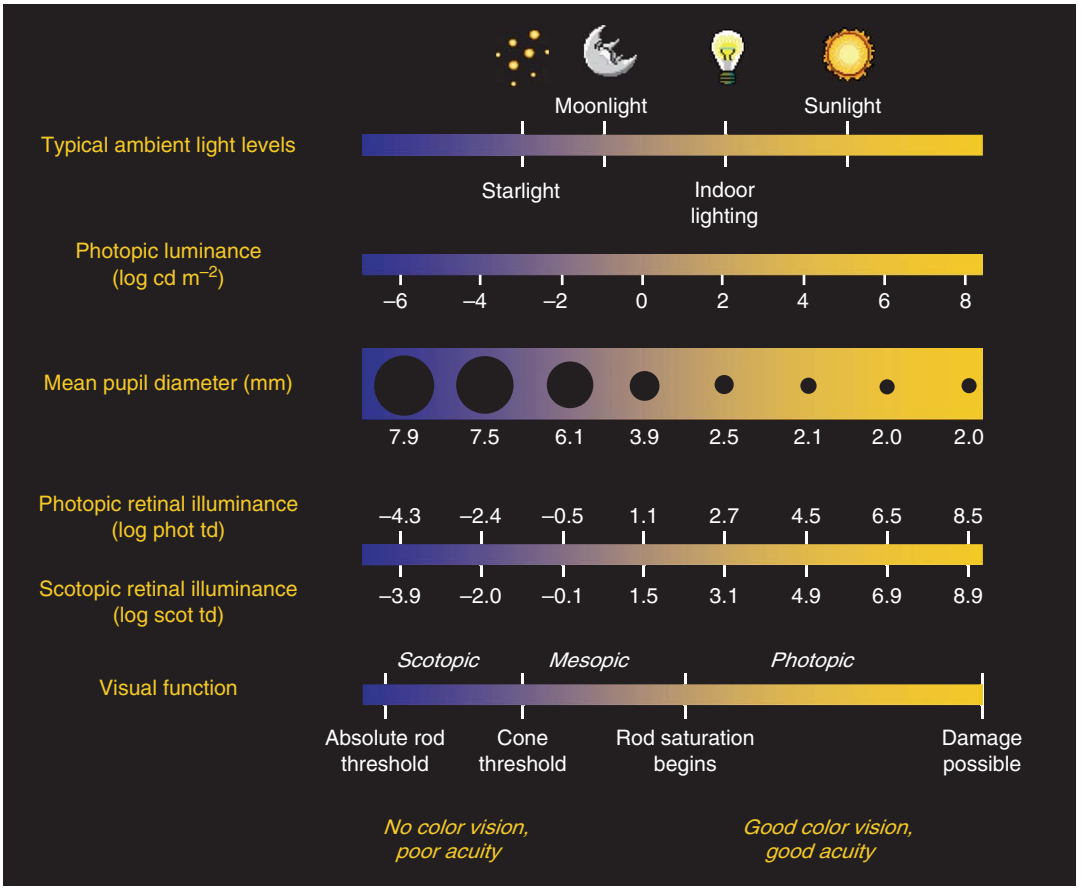

Figure 1 Illumination levels. Typical ambient light levels are compared with photopic luminance (log cd. m^{-2}), mean pupil diameter (mm), photopic and scotopic retinal illuminance (log photopic and scotopic tds, respectively), and visual function. The scotopic, mesopic, and photopic regions are defined according to whether rods alone, rods and cones, or cones alone operate. The conversion from photopic to scotopic values assumes a white standard CIE D_{65} illumination. Figure based in part on the design of Hood, D. C. and Finkelstein, M. A. 1986. Sensitivity to Light. In: Handbook of Perception and Human Performance (*eds*. K. Boff, L. Kaufman, and J. Thomas), pp. 5–1–5–66. Wiley.

2.06.1.2 Color Matching Functions

Because normal human photopic vision is trichromatic, the color of a light can be defined by just three variables: the intensities of three specially chosen primary lights that match it. Figure 2 shows examples of the $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ color matching functions (CMFs) for red–green–blue (RGB) primaries of 645, 526, and 444 nm. Each CMF defines the amount of that primary required to match monochromatic targets of equal energy. CMFs can be determined without any knowledge of the underlying cone spectral sensitivities. The only restriction on the choice of primary lights is that they must be independent – in the sense that no two will match the third.

CMFs can be linearly transformed to any other set of real primary lights, and, as illustrated in Figure 2, to imaginary primary lights, such as the all-positive X, Y, and Z primaries favored by the CIE to define international lighting standards, or to the L, M and S cone fundamental primaries, which are physiologically relevant. The three cone fundamental primaries (or Grundempfindungen – fundamental sensations) are the three imaginary primary lights that would uniquely stimulate each of the three cones to yield $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$, or the L-, M-, and S-cone spectral sensitivity functions. For convenience and precision, cone spectral sensitivities are usually defined in terms of transformed CMFs (see Section 2.06.2.3), rather than as raw sensitivity measurements (like those shown in Figure 3, below). Notice that for the R, G, and B primaries, one of the CMFs is negative over the region of the spectrum where three primaries are required, which indicates that

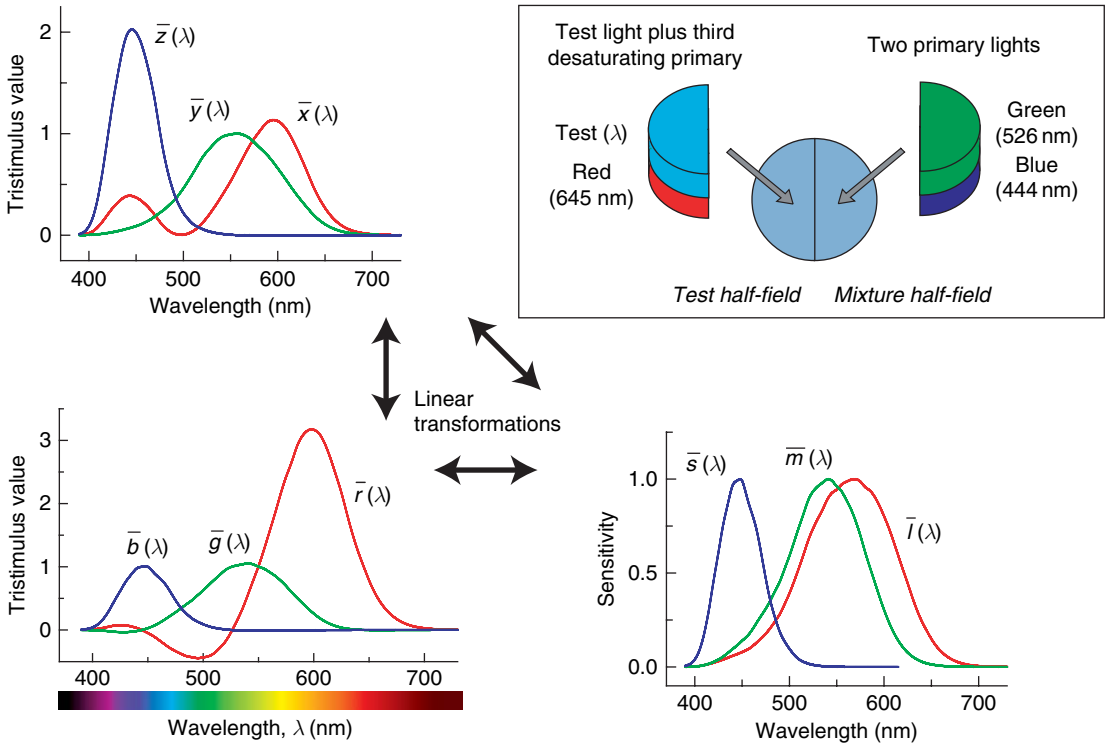

Figure 2 Upper right inset: Maximum saturation method of color matching using spectral lights. A monochromatic test field of wavelength, λ, is matched to a mixture of red (645 nm), green (526 nm), and blue (444 nm) monochromatic primary lights, one of which, as in this example, may have to be added to the test field to complete the match. The amounts of each of the three primaries required to match monochromatic lights spanning the visible spectrum are known as the red, $\bar{r}(\lambda)$, green, $\bar{g}(\lambda)$, and blue, $\bar{b}(\lambda)$ color matching function (CMFs; red, green, and blue lines, respectively) shown in the lower left panel. A negative sign means that that primary must be added to the target to complete the match. CMFs can be linearly transformed from one set of primaries to another. Also illustrated here are CMFs for the imaginary X, Y, and Z primaries (top left) and the cone fundamental L, M, and S primaries (bottom right). The CMFs are transformations of the Stiles W. S. and Burch J. M. (1959) 10-deg CMFs. The fundamentals are the 10-deg cone fundamentals of Stockman A. and Sharpe L. T. (2000).

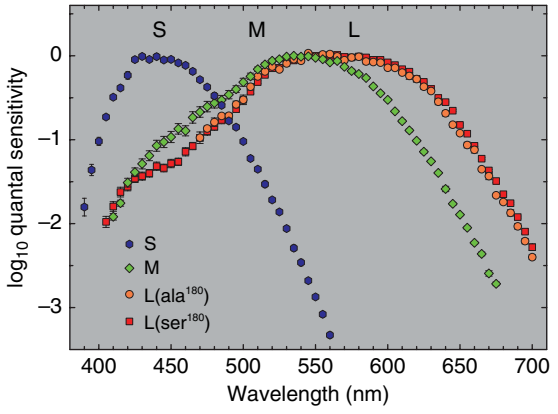

Figure 3 Mean spectral sensitivity data. L-cone data from 17 L(ser^{180}) subjects (red squares), five L(ala^{180}) subjects (orange circles), and M-cone data from nine L1M2/L2M3 protanopes (green diamonds) measured by Sharpe L. T. *et al.* (1998); and S-cone data from five normals and three blue-cone monochromats (blue hexagons) measured by Stockman A. *et al.* (1999).

the primary in question has to be added to the test light in order to complete the match. This does not violate the trichromatic principle, but simply reflects the fact that real primaries excite more than one cone type (see Figures 3 and 4), with the result that no triad of such primaries can completely enclose the three-dimensional space of physically realizable colors. For a further discussion about colorimetry, and its link to the cone fundamentals, see Stockman A. and Sharpe L. T. (1999) and Stockman A. (2003).

2.06.1.3 Dichromacy and Monochromacy

Some people have reduced forms of normal trichromat color vision. Dichromats, who lack one of the three cone photoreceptor types and can therefore match test lights to a mixture of just two primary lights, fall into three classes: protanopes, deuteranopes, and tritanopes, who lack the L-, M-, and S-cones,

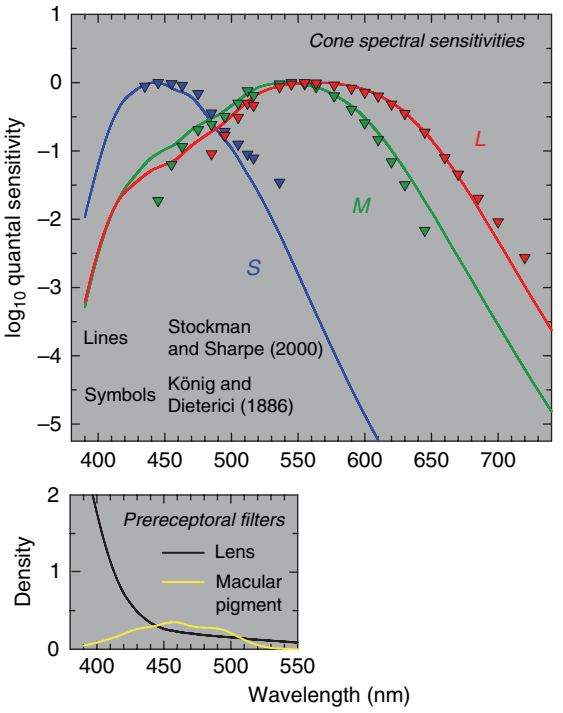

Figure 4 S-, M-, and L-cone 2-deg spectral sensitivity estimates of Stockman A. and Sharpe L. T. (2000), based on linear transformations of the Stiles W. S. and Burch J. M. (1959) 10-deg RGB color matching function (CMFs), determined by the mean spectral sensitivity data shown in Figure 3 as a guide, (colored lines) compared with the historical estimates of König A. and Dieterici C. (1886) (colored triangle). The lower inset shows the mean macular density spectrum for a 2-deg field (yellow line) based on measurements by Bone R A. *et al.* (1992), and the mean lens density spectrum of van Norren D. and Vos J. J. (1974) slightly adjusted by Stockman A. *et al* (1999) (black line).

respectively. Most estimates of the cone spectral sensitivities (see below) depend on the use of dichromats and the assumption – known as the loss, reduction, or König hypothesis – that their remaining cone classes are normal (Maxwell, J. C., 1860; König, A. and Dieterici, C., 1886). This approach now has a much firmer foundation, since it is possible to use molecular genetics to select those dichromats who truly conform to the reduction hypothesis (Nathans, J. *et al.*, 1986a; 1986b). Appropriate selection is important, because some red–green or X-linked dichromats have an LM-hybrid cone photopigment with a spectrally shifted spectral sensitivity, while others have multiple cone photopigments (LM-hybrid plus normal) with slightly different spectral sensitivities. If an individual has an LM-hybrid and a normal photopigment that differ sufficiently from one another, that person will usually retain some (reduced) trichromacy and be classed as an anomalous trichromat (see Section 2.06.4.1).

Monochromats can match test lights to just one primary light. In principle, they can lack two of the three cone types (S-, M-, and L-cone monochromats) or all three of them (rod monochromats, or complete achromats). S-cone (or blue-cone) monochromats (Blackwell, H. R. and Blackwell, O. M., 1957; 1961) are particularly useful for measuring S-cone spectral sensitivity (see Section 2.06.2.2). For an extended discussion of color deficiencies and their molecular origins, see Sharpe L. T. *et al.* (1999).

2.06.2 Cone Spectral Sensitivities

Since the establishment of trichromatic color theory (e.g., Young, T., 1802; von Helmholtz, H. L. F., 1852; Maxwell, J. C., 1855), a central goal of color science has been the accurate determination of the three cone spectral sensitivities, $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$. Studies of human cone spectral sensitivity have encompassed many fields of inquiry, including fundus reflectometry (e.g., Rushton, W. A. H., 1965), microspectrophotometry (e.g., Dartnall, H. J. *et al.*, 1983), suction electrode recordings (e.g., Schnapf, J. L. *et al.*, 1987; Kraft, T. W. *et al.*, 1998), electroretinography (e.g., Neitz, J. *et al.*, 1995), and absorption spectroscopy (Oprian, D. D. *et al.*, 1991; Merbs, S. L. and Nathans, J., 1992a; 1992b; Asenjo, A. B. *et al.*, 1994). Our primary focus will be visual psychophysics, which provides the most extensive and accurate *in vivo* spectral sensitivity data.

2.06.2.1 Historical Overview

Arguably, the first plausible psychophysical estimates of $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$ were obtained by König A. and Dieterici C. (1886; see Figure 4). Since then, many other estimates have been made, notably those by Bouma P. J. (1942), Judd D. B. (1945; 1949), Wyszecki G. and Stiles W. S. (1967), Vos J. J. and Walraven P. L. (1971), Vos J. J. (1978), Estévez O. (1979), Vos J. J. *et al.* (1990), and Stockman A. *et al.* (1993a). These have been discussed elsewhere (e.g., Parsons, J. H., 1924; Boring, E. G., 1942; Le Grand, Y., 1968; Stockman, A. and Sharpe, L. T., 1999). Until recently, the estimates by Smith V. C. and Pokorny J. (1975) have been widely used in science and research as a *de facto* standard. Newer estimates by Stockman A.

and Sharpe L. T. (2000) have been proposed as a new CIE standard for physiologically relevant fundamental primaries.

2.06.2.2 Cone Spectral Sensitivity Measurements

Although the cone fundamentals can be estimated by comparing dichromatic and normal color matches (Maxwell, J. C., 1855; 1856), the most straightforward method is to measure the cone spectral sensitivities directly. Because the three cone types peak in sensitivity in different parts of the spectrum, and their spectral sensitivities overlap extensively, spectral sensitivity measurements reflect the activity of more than one cone type. The isolation of the response of a single cone type over substantial regions of the spectrum requires special procedures to favor the wanted cone type and disfavor the two unwanted ones; or it requires the use of dichromats or monochromats, who lack one or two of the cone types. A now classical approach is to use selective chromatic adaptation (e.g., Stiles, W. S., 1939; 1978) and to present a target of variable wavelength on a larger adapting or background field of a second wavelength (or mixture of wavelengths) that selectively suppresses the sensitivities of the two unwanted cone types. However, cone isolation in normal observers becomes increasingly difficult as the wavelength of the target approaches the wavelength of the background, because any advantage gained by the background's selective suppression of the unwanted cone types is offset by the target selectively favoring detection by the unwanted cone types. Complete isolation can be achieved, but only if the selective sensitivity losses due to adaptation by the background exceed the selective effect of the target (e.g., King-Smith, P. E. and Webb, J. R., 1974; Eisner, A. and MacLeod, D. I. A., 1981; Stockman, A. and Mollon, J. D., 1986; Stockman, A. *et al.*, 1993a). Data obtained in normals can be effectively used to complement and verify much more easily isolated cone spectral sensitivity data measured in monochromats and dichromats who lack one or two of the three normal cone types (for such comparisons, see figures 3–5 of Stockman, A. and Sharpe, L. T., 2000). Now that the approach of using data from color deficient observers to model normal color vision has a firm molecular genetic foundation, it is in many ways the more preferable approach.

With the S-cones disadvantaged or suppressed, L- and M-cone spectral sensitivities can be directly measured in deuteranopes who lack M-cone function and in protanopes without L-cone function. Figure 3 shows the mean spectral sensitivity data obtained from seventeen single-gene L(ser^{180}) deuteranopes with serine at position 180 of their L-cone photopigment opsin gene (red squares), from five single-gene L(ala^{180}) deuteranopes with alanine at position 180 (orange circles), and from nine L1M2/L2M3 protanopes (green diamonds). For further details, see Sharpe, L. T. *et al.*, 1998; Stockman, A. and Sharpe, L. T., 2000. The two mean L-cone functions, which are separated by ~2.7 nm in λ_{max} (Sharpe, L. T. *et al.*, 1998), reflect the two commonly occurring L-cone photopigment polymorphisms (see Section 2.06.4.1). An overall L-cone mean was also derived (not shown) to reflect the proportions of the two polymorphic variants in the population (Stockman, A. and Sharpe, L. T., 2000). This was used to determine the mean L-cone fundamentals (see Section 2.06.2.3).

S-cone spectral sensitivity is most easily measured throughout the spectrum in S-cone monochromats (e.g., Blackwell, H. R. and Blackwell, O. M., 1961; Grützner, P., 1964; Alpern, A. *et al.*, 1965; Alpern, M. *et al.*, 1971; Daw, N. W. and Enoch, J. M., 1973; Smith, V. C. *et al.*, 1983; Hess, R. F. *et al.*, 1989). In defining a mean S-cone spectral sensitivity, Stockman A. *et al.* (1999) measured S-cone spectral sensitivities in three blue-cone monochromats known to lack L- and M-cones on genotypical as well as phenotypical grounds, and combined them with S-cone data from normals obtained at short and middle wavelengths on an intense yellow background field that selectively adapted the M- and L-cones. Their mean S-cone function is shown in Figure 3 (blue hexagons).

2.06.2.3 From Cone Spectral Sensitivities to Color Matching Functions

Although the cone spectral sensitivities could be defined as the direct sensitivity measurements shown in Figure 3, it is customary to define them in terms of linear combinations of a set of CMFs, which are – in principle at least – more precise. All that is required is to find the linear combinations of $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ that best fits each cone spectral sensitivity, as defined above, allowing adjustments in the densities of prereceptoral filtering and photopigment optical density in order to account for differences in the mean densities between different populations (these factors are age- and race-dependent and highly variable between individuals) and to account for differences in retinal area (because the filtering densities change with retinal eccentricity; see Section 2.06.4).

The significance of the best-fitting linear combination can be stated formally. When an observer matches the test and mixture fields in a color matching experiment, the two fields are matched for each of his or her three cones types. The match, in other words, is a match at the level of the cones, thus:

$$\begin{aligned}\bar{l}_R\bar{r}(\lambda)+\bar{l}_G\bar{g}(\lambda)+\bar{l}_B\bar{b}(\lambda)&=\bar{l}(\lambda)\\ \bar{m}_R\bar{r}(\lambda)+\bar{m}_G\bar{g}(\lambda)+\bar{m}_B\bar{b}(\lambda)&=\bar{m}(\lambda)\\ \bar{s}_R\bar{r}(\lambda)+\bar{s}_G\bar{g}(\lambda)+\bar{s}_B\bar{b}(\lambda)&=\bar{s}(\lambda)\end{aligned} \quad [1]$$

where $\bar{l}_R, \bar{l}_G$, and $\bar{l}_B$ are, respectively, the L-cone sensitivities to the R, G, and B primary lights, and similarly $\bar{m}_R, \bar{m}_G$, and $\bar{m}_B$ and $\bar{s}_R, \bar{s}_G$, and $\bar{s}_B$ are the analogous M- and S-cone sensitivities. Since the S-cones are insensitive in the red, it can be assumed that $\bar{s}_R$ is effectively zero for a long-wavelength R primary. There are therefore eight unknowns required for the linear transformation:

$$\begin{pmatrix}\bar{l}_R & \bar{l}_G & \bar{l}_B\\ \bar{m}_R & \bar{m}_G & \bar{m}_B\\ 0 & \bar{s}_G & \bar{s}_B\end{pmatrix}\begin{pmatrix}\bar{r}(\lambda)\\ \bar{g}(\lambda)\\ \bar{b}(\lambda)\end{pmatrix}=\begin{pmatrix}\bar{l}(\lambda)\\ \bar{m}(\lambda)\\ \bar{s}(\lambda)\end{pmatrix} \quad [2]$$

Because we are only concerned about the relative shapes of $\bar{l}(\lambda), \bar{m}(\lambda)$, and $\bar{s}(\lambda)$, the eight unknowns collapse to just five:

$$\begin{pmatrix}\bar{l}_R/\bar{l}_B & \bar{l}_G/\bar{l}_B & 1\\ \bar{m}_R/\bar{m}_B & \bar{m}_G/\bar{m}_B & 1\\ 0 & \bar{s}_G/\bar{s}_B & 1\end{pmatrix}\begin{pmatrix}\bar{r}(\lambda)\\ \bar{g}(\lambda)\\ \bar{b}(\lambda)\end{pmatrix}=\begin{pmatrix}k_l\bar{l}(\lambda)\\ k_m\bar{m}(\lambda)\\ k_s\bar{s}(\lambda)\end{pmatrix} \quad [3]$$

where the absolute values of $k_l\left(1/\bar{l}_B\right), k_m(1/\bar{m}_B)$, and $k_s(1/\bar{s}_B)$ remain unknown, but are typically chosen to scale three functions in some way: for example, so that $k_l\bar{l}(\lambda), k_m\bar{m}(\lambda)$, and $k_s\bar{s}(\lambda)$ peak at unity. The five unknowns in Eqn. (3), $\bar{l}_R/\bar{l}_B, \bar{l}_G/\bar{l}_B, \bar{m}_R/\bar{m}_B, \bar{m}_G/\bar{m}_B$, and $\bar{s}_G/\bar{s}_B$, can then be estimated by directly fitting CMFs to the Stockman A. and Sharpe L. T. (1999) cone spectral sensitivity data shown in Figure 3. The transformation matrix for the Stiles W. S. and Burch J. M. (1959) 10-deg RGB CMFs, on which the Stockman A. and Sharpe L. T. (2000) cone fundamentals are based, is:

$$\begin{pmatrix}2.846201 & 11.092490 & 1\\ 0.168926 & 8.265895 & 1\\ 0 & 0.010600 & 1\end{pmatrix} \quad [4]$$

This transformation is illustrated in Figure 2. The transformation matrix given in eqn [4] multiplied by the CMFs (which are in energy units) yields cone fundamentals in energy units. To convert to quantal units multiply by λ^{-1}. The values of k_l, k_m, and k_s in eqn [3] depend on the desired normalization and on the units (energy or quanta). More details can be found in Stockman A. *et al.* (1999) and in Stockman A. and Sharpe L. T. (2000).

Figure 4 shows the current 2-deg estimates of Stockman A. and Sharpe L. T. (2000) (colored lines) compared with the much earlier estimates obtained 120 years ago by König A. and Dieterici C. (1886) (colored triangles). The Stockman A. and Sharpe L. T. 2-deg estimates are based on a transformation of the Stiles W. S. and Burch J. M. (1959) 10-deg CMFs given by eqn [4] adjusted to 2-deg by correcting for changes in photopigment optical density and macular pigment density (for details, see Stockman, A., and Sharpe, L. T., 2000). These 10-deg CMFs, which were measured in 49 subjects from approximately 390 to 730 nm (and in nine subjects from 730 to 830 nm), were chosen as the basis of the 2-deg cone fundamentals because they are the most secure set of existing color matching data, and are available as individual as well as mean data.

2.06.2.4 Rod Spectral Sensitivity Measurements

Because there is only a single type of rod photoreceptor, rod spectral sensitivity is achromatic and univariant and may be measured by any method that excludes detection being mediated by the less sensitive cones (e.g., scotopic luminance levels should be used). It is identical with scotopic luminous efficiency (see Section 2.06.3.1.1 and Figure 5).

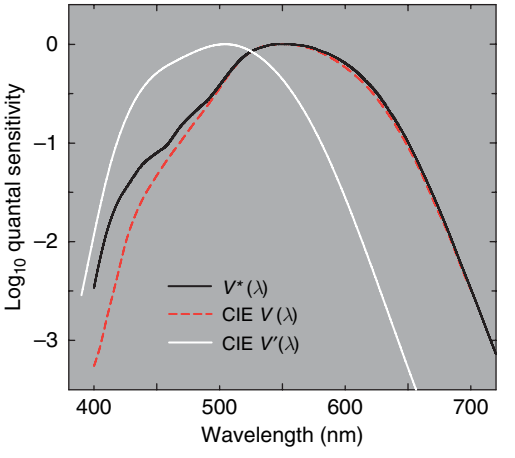

Figure 5 The Commission Internationale de l'Eclairage (CIE) scotoptic $V'(\lambda)$ (white line) and 1924 photopic $V(\lambda)$ (red dashed line) functions. The recent, photopic luminous efficiency function, $V*(\lambda)$, proposed by Sharpe L. T. *et al.* (2005) is shown by the black line.

2.06.3 Achromatic and Chromatic Spectral Sensitivity

When spectral sensitivity is measured under most practical conditions, it will inevitably involve detection by more than one photoreceptor type. Such spectral sensitivities are potentially complex, since they typically reflect interactions that occur between photoreceptor signals in different postreceptoral channels. One simplification has been to measure the spectral sensitivity of achromatic or luminance mechanisms (or luminous efficiency) separately from those of chromatic ones.

2.06.3.1 Achromatic Luminous Efficiency

Luminous efficiency is a measure of spectral sensitivity that might be described as a measure of apparent intensity. It is actually defined as the effectiveness of lights of different wavelength in specific matching or detection tasks. The term was introduced by the International Lighting Commission (CIE) to provide a psychophysical or perceptual analog of radiance, called luminance. Luminous efficiency has been defined for scotopic, photopic, and mesopic illumination levels.

2.06.3.1.1 Scotopic luminous efficiency

Scotopic luminous efficiency is comparatively straightforward, since it depends on the activity of a single univariant photoreceptor type, the rods. Thanks to univariance, scotopic luminous efficiency fulfils the basic requirement of any system of photometry that the luminous efficiency of any mixture of lights is the sum of the efficiencies of the components of the mixture; otherwise known as Abney's Law (Abney, W. d. W. and Festing, E. R., 1886; Abney, W. d. W., 1913). Figure 5 shows the scotopic CIE 1951 $V'(\lambda)$ function (white line), which is based on original data from Crawford B. H. (1949) and Wald G. (1945).

2.06.3.1.2 Photopic Luminous Efficiency

Photopic luminous efficiency, $V(\lambda)$, is complicated by the fact that there are considerable differences between the efficiency functions obtained by different measurement procedures and criteria, which include heterochromatic flicker photometry (HFP) or minimum flicker, a version of minimum flicker called heterochromatic modulation photometry (HMP), direct heterochromatic brightness matching, step-by-step brightness matching, minimally distinct border (MDB), minimum motion, color matching, absolute threshold, increment threshold, visual acuity, and critical flicker frequency (for reviews, see Wagner, G. and Boynton, R. M., 1972; Wyszecki, G. and Stiles, W. S., 1982; Lennie, P. *et al.*, 1993; Stockman, A. and Sharpe, L. T., 1999).

Although $V(\lambda)$ is often treated as if it were comparable to the spectral sensitivity of a univariant photoreceptor, it is not: it depends on the activity of more than one photoreceptor type. Thus, unlike $V'(\lambda)$, additivity is not inevitable, but requires the adoption of special tasks, the performance of which is supposed to depend on an additive luminance mechanism. Such tasks include HFP, in which continuously alternating lights of different wavelength are matched in luminance to minimize the perception of flicker, and MDB, in which the relative intensities of the two half fields is set so that the border between them appears minimally distinct (e.g., Sperling, H. G., 1958; Wagner, G. and Boynton, R. M., 1972). The generality of such luminous efficiency functions are severely limited, however, since their spectral sensitivities are strongly dependent on chromatic adaptation (e.g., De Vries, H., 1948; Eisner, A. and MacLeod, D. I. A., 1981; Stockman, A. *et al.*, 1993b). In other words, the shapes of measured luminous efficiency functions vary with the adapting condition, even though functions like $V(\lambda)$ and $V^*(\lambda)$ (see below) have a fixed shape.

Nevertheless, a luminous efficiency function is of practical use in many applications, especially for conditions that are similar to those under which the function was defined (e.g., neutral adaptation). Unfortunately, however, the standard CIE photopic 1924 $V(\lambda)$ function is seriously in error. It is a speculative hybrid function, artificially smoothed, and dubiously constructed from divergent data measured under very different procedures at several laboratories (Wyszecki, G. and Stiles, W. S., 1982). The CIE $V(\lambda)$ function shown in Figure 5 as the dashed red line substantially underestimates luminous efficiency at short wavelengths. Attempts to improve it (Judd, D. B., 1951; Vos, J. J., 1978) have been less than satisfactory (Stockman, A. and Sharpe, L. T., 1999; 2000), and have been little used outside vision science laboratories.

Recently, Sharpe L. T. *et al.* (2005) have proposed a new luminous efficiency function, $V^*(\lambda)$, which is based on experimentally determined 25-Hz, 2-deg

diameter, HFP data from 40 observers of known genotype, taking into account the polymorphism of the L-cone photopigment. $V^*(\lambda)$ defines luminance for a reproducible, phase of natural daylight (CIE standard illuminant D_{65} adaptation), while being a linear combination of the Stockman A. and Sharpe L. T. (2000) M- and L-cone fundamentals. The $V^*(\lambda)$ function (black line) is shown in Figure 5. In terms of the Stockman A. and Sharpe L. T. (2000) M- and L-cone quantal fundamentals normalized to unity peak, the quantal $V^*(\lambda) = [1.891\bar{l}(\lambda) + \bar{m}(\lambda)]/2.80361$; whereas, in terms of the Stockman A. and Sharpe L. T. (2000) M- and L-cone energy fundamentals normalized to unity peak, the energy-based $V^*(\lambda) = [1.98065\bar{l}_e(\lambda) + \bar{m}_e(\lambda)]/2.87091$. The different weights and scaling factors simply reflect the different unity normalizations in quantal and energy units. Note that these constants define $V^*(\lambda)$, which was determined for adaptation to the D_{65} daylight standard; different adaptation conditions would lead to different constants and different efficiency functions.

2.06.3.1.3 Mesopic Luminous Efficiency

Mesopic luminous efficiency has been measured in several laboratories using a variety of methods (e.g., Walters, H. V. and Wright, W. D., 1943; Kinney, J. A. S., 1958; Palmer, D. A., 1968; Kokoschka, S., 1972; Yaguchi, H. and Ikeda, M., 1984; Nakano, Y. and Ikeda, M., 1986; Sagawa, K. and Takeichi, K., 1986; Viénot, F. and Chiron, F., 1992; He, Y. *et al.*, 1998). The main challenge of mesopic photometry is to characterize how the luminous efficiency changes between the scotopic and photopic levels. The modeling, however, has proven to be difficult, since the relationship between mesopic luminous efficiency and $V(\lambda)$ and $V'(\lambda)$ is complex and nonlinear. Such complexities are inevitable because of the substantial and often rapid changes in the spatial and temporal properties of the visual system that accompany the transition from scotopic to photopic vision. These are caused not only by the change from rod to cone photoreceptors, but also by changes between the different postreceptoral pathways through which the rod and cone signals are transmitted. For a recent review, see Stockman A. and Sharpe L. T., 2006.

2.06.3.2 Chromatic Spectral Sensitivity

Spectral sensitivities measured under conditions that are not specially chosen to yield additive data typically reflect the interaction of complex processes. Generally the shape of the sensitivity curve becomes broader and has pronounced notches and humps (e.g., Stiles, W. S. and Crawford, B. H., 1933; Sperling, H. G. and Harwerth, R. S., 1971; King-Smith, P. E. and Carden, D., 1976; Kranda, K. and King-Smith, P. E., 1979; Thornton, J. E. and Pugh, E. N., Jr., 1983; Kalloniatis, M. and Sperling, H. G., 1990). These characteristics can be accounted for by detection being mediated by chromatic, cone-opponent mechanisms in addition to achromatic ones. Thus, the so-called Sloan's notch (Sloan, L. L., 1928) occurs at target wavelengths at which the target produces the same chromatic signal as the background, so that it cannot be detected by the chromatic mechanism, and is instead detected by a less sensitive achromatic one; by contrast, the humps correspond to target wavelengths at which the target produces a large chromatic signal with respect to the background (e.g., Ingling, C. R., Jr., 1969; Sperling, H. G. and Harwerth, R. S., 1971; King-Smith, P. E. and Carden, D., 1976; Kranda, K. and King-Smith, P. E., 1979; Thornton, J. E. and Pugh, E. N., Jr., 1983; Kalloniatis, M. and Sperling, H. G., 1990; Calkins, D. J. *et al.*, 1992).

Chromatic detection is treated further in Chapter Chromatic Detection and Discrimination. By replotting these types of spectral sensitivity data in cone contrast space, the importance of detection by chromatic and luminance mechanisms becomes much clearer (e.g., Stromeyer, C. F., III *et al.*, 1985; Kalloniatis, M. and Sperling, H. G., 1990; Chaparro, A. *et al.*, 1995; Eskew, R. T. *et al.*, 1999). Spectral sensitivity measurements are now of little value in studying chromatic mechanisms, which are better studied using more complex stimuli that produce chromatic modulations (e.g., modulations of opposite signs in the M- and L-cones). It should be noted, however, that the production of these complex stimuli is still critically dependent on a precise knowledge of the underlying cone spectral sensitivities.

2.06.4 Other Factors that Influence Spectral Sensitivity

Several other factors influence spectral sensitivities and color matches. The most important ones arise from individual differences among observers, and so should be taken into account when trying to predict the spectral sensitivities of an individual from standard or mean functions. Some of them vary with retinal position, and so should be considered when

trying to predict the spectral sensitivities for retinal areas or retinal positions that differ from the centrally viewed 2-deg or 10-deg areas used to obtain the standard functions.

2.06.4.1 Photopigment Variability and Anomalous Trichromacy

There is now clear molecular genetic, psychophysical, and electroretinographic evidence that the M- and L-cone photopigments can vary in spectral position between observers (for a review, see Sharpe, L. T. *et al.*, 1999), thus confirming earlier evidence for such shifts (e.g., Alpern, M. and Pugh, E. N., Jr., 1977; Dartnall, H. J. A. *et al.*, 1983; MacLeod, D. I. A. and Webster, M. A., 1983; Alpern, M., 1987; Webster, M. A. and MacLeod, D. I. A., 1988). These shifts are caused by the inheritance of hybrid LM or ML cone photopigment opsin genes, which are fusion genes produced by intragenic crossing over, containing the coding sequences of both L- and M-cone pigment genes. Both *in vitro* and *in vivo* measurements of the absorbance spectrum peaks of the hybrid pigments reveal a wide range of possible anomalous pigments lying between the normal L- and M-cone pigments. Rather than a continuous distribution, there is a clustering of LM hybrid pigments having their peak absorbances within about 8 nm of the peak absorbance of the normal M-cone pigment and a clustering of ML hybrid pigments having their peak absorbances within about 12 nm of the peak absorbance of the normal L-cone pigment (see table 1 of Stockman, A. *et al.*, 2000). Smaller shifts occur within the normal population, because of different polymorphisms (commonly occurring allelic differences) of the M- and L-cone photopigment opsin genes. The two common polymorphic variants of the L-cone photopigment (which have either alanine or serine at position 180 of the L photopigment opsin gene) differ in spectral position by 2.7 nm or more. The same polymorphic variation occurs in the M-cone photopigment, with a similar shift in spectral sensitivity, but the serine variant is rather rare (see Sharpe, L. T. *et al.*, 1999).

Hybrid LM and ML pigments in people with otherwise normal photopigments result in anomalous trichromacy. Individuals with a hybrid LM pigment replacing one of the two polymorphic variants of the normal L cone pigment are known as protanomalous trichromats; whereas those with a hybrid ML pigment replacing one of the two polymorphic variants of the normal M cone pigment are known as deuteranomalous trichromats. The color vision deficits of anomalous trichromats are usually less severe than those of dichromats, but there is considerable variability among individuals. In general, the smaller the separation between the spectral sensitivities of the normal and anomalous hybrid pigments, the poorer the anomalous trichromat's color discrimination (for more details, see Sharpe, L. T. *et al.*, 1999). Anomalous trichromacy can sometimes arise in individuals lacking either the normal L- or M-cone photopigment because of photopigment optical density differences between photoreceptors containing ostensibly the same remaining L- or M-cone photopigment (Neitz, J. *et al.*, 1999).

2.06.4.2 Lens Pigment

Light is brought into focus on the retina by the cornea and the pigmented crystalline lens. The pigment in the lens absorbs light mainly of short wavelengths (see lower inset of Figure 4, black line). Individual differences in lens pigment density can be large with a range of approximately $\pm 25\%$ of the mean density in young observers (<30 years old; see van Norren, D. and Vos, J. J., 1974). Since lens density increases with the age of the observer (e.g., Crawford, B. H., 1949; Said, F. S. and Weale, R. A., 1959; Pokorny, J. *et al.*, 1988), the variability in the general population is even larger. A two-factor model has been proposed to account for changes in lens density spectrum with age (Pokorny, J. *et al.*, 1988; Xu, J. *et al.*, 1997). Stockman, A. *et al.* (1999) have proposed a slightly adjusted version of the mean lens density spectrum of van Norren D. and Vos J. J. (1974) that is consistent with the Stockman A. and Sharpe L. T. (2000) cone fundamentals.

2.06.4.3 Macular Pigment

Before reaching the photoreceptor, light must pass through the ocular media, including, at the fovea, the macula lutea, which contains macular pigment. This pigment also absorbs light mainly of short wavelengths (see lower inset of Figure 4, yellow line). Individual differences in its density can also be large with a range of peak density from 0.0 to *c.* 1.2 at 460 nm (Wald, G., 1945; Bone, R. A. and Sparrock, J. M. B., 1971; Pease, P. L. *et al.*, 1987). The density of the pigment changes with retinal location; tending to become more transparent with eccentricity. It is

wholly or largely absent by a retinal eccentricity of 10 deg (e.g., Bone, R. A. *et al.*, 1988). Stockman A. and Sharpe L. T. (2000) have proposed a mean macular density spectrum based on measurements by Bone R. A. *et al.* (1992) that is consistent with their cone fundamentals.

2.06.4.4 Photopigment Optical Density

The axial optical density of the photopigment in the receptor outer segment varies between individuals. Estimates of photopigment optical density vary considerably depending to a large extent on the method used to estimate them, but all estimates show sizeable individual differences (e.g., Terstiege, H., 1967; Miller, S. S., 1972; King-Smith, P. E., 1973b, 1973a; Smith, V. C. and Pokorny, J., 1973; Alpern, M., 1979; Burns, S. A. and Elsner, A. E., 1993; Berendschot, T. T. J. M. *et al.*, 1996). Decreases in photopigment optical density result in a narrowing of cone spectral sensitivity curves, which cause corresponding changes to their linear transformations, the CMFs. Any corrections are most easily applied to the cone fundamentals rather than the CMFs. For further details and the relevant equations, see Stockman A. and Sharpe L. T. (1999), eqns [9]–[12].

2.06.4.5 Changes with Eccentricity

Macular pigment and photopigment optical density both decline with eccentricity. Consequently, cone spectral sensitivities, which are defined for centrally viewed 2- or 10-deg diameter fields, must be adjusted in order to predict accurately color matches for other viewing conditions – either for different field sizes or for different viewing angles.

One additional complication is that the S-cones are absent in approximately the central 25 min diameter of vision, so that in that region color matches become tritanopic (e.g., König, A., 1894; Thomson, L. C. and Wright, W. D., 1947; Willmer, E. N., 1950; Williams, D. R. *et al.*, 1981). The small-field tritanopic effect may also occur with steady fixation of parafoveal fields (Hartridge, H., 1945; Thomson, L. C. and Wright, W. D., 1947). The exclusion of the S-cones from the very central fovea is usually attributed to the need to counteract the deleterious effects of light scattering and axial chromatic aberration on spatial resolution, which cause blurring and/or defocus particularly at short wavelengths (but see McClellan, J. S. *et al.*, 2002). For most practical purposes, small field tritanopia can be largely ignored, however, because its influence on color matching and discrimination is mitigated by the blur introduced by the optics of the eye and constant microsaccades (Bedford, R. E. and Wyszecki, G., 1958; McCree, K. J., 1960).

2.06.5 Conclusions

A precise knowledge of the spectral sensitivity of the human rod and cone photoreceptors is central to our understanding and modeling of vision and visual function in normals and individuals with color vision deficiencies. For the rods, spectral sensitivity and luminous efficiency are identical and both are defined by the CIE 1951 $V'(\lambda)$ function. For the cones, the 2-deg and 10-deg cone fundamentals, and the associated lens and macular pigment and photopigment templates, of Stockman A. and Sharpe L. T. (2000), and the photopic luminous efficiency functions of Sharpe L. T. *et al.* (2005) provide a consistent set of standard functions with which to model human vision. These functions, and others, can be downloaded from the Color and Vision Research Laboratories' website.

Glossary

cardinal axes Color directions defined by an exchange of L- and M-cone excitations at constant luminance, an S-cone excitation direction, and a luminance direction.

cardinal mechanisms Bipolar chromatic mechanisms that are stimulated in isolation by colored stimuli varying along the three cardinal axes. Generally referred to as red–green, blue–yellow, and luminance mechanisms.

classical mechanisms Six unipolar chromatic mechanisms, R (red), G (green), B (blue), Y (yellow), I (increment), and D (decrement). When arranged in pairs (R/G, B/Y, I/D) these are similar to the cardinal mechanisms.

chromatic mechanism A psychophysical construct, based upon a linear or nonlinear combination of cone signals. The inputs to a mechanism are assumed to have undergone cone-specific adaptation; the outputs are univariant and labeled-line.

cone excitation A number representing the quantal or energy catch of an L, M, or S cone.

cone contrast A dimensionless number representing the relative quantal or energy catch of an L, M, or S cone, for example $\Delta L/L$. The numerator represents a change in quantal catch due to a stimulus modulation, the denominator represents the quantal catch to which the cone is adapted.

cone contrast space A color space with axes representing the cone contrasts produced by a stimulus modulation. The origin represents the mean or prevailing illumination; stimulus directions are normally specified by vectors in the three-dimensional space or planes within it, and strengths by the cone contrast vector length (or, alternatively, root mean square).

chromatic bandwidth A measurement of the region of color space to which a mechanism is sensitive. Normally measured by use of field methods.

cone opponency A type of combination of cone inputs to a chromatic mechanism, in which two of the signals have opposing effects within a single mechanism. Compare with *color opponency*.

color opponency A perceptual or phenomenological opposition of color, in which the possible outputs of a color mechanism have two qualitatively different and nonoverlapping (mutually exclusive) ranges, for example, red and green. Compare with *cone opponency*.

cone-specific adaptation Adaptation to light that acts on the signals generated by a single class of cone photoreceptor.

detection contour A set of thresholds measured in a plane of some color space, such as cone excitation or cone contrast space.

DKL (Derrington Krauskopf Lennie) space A version of a cone excitation space in which the axes are aligned with the three cardinal mechanism

axes. Often parameterized in spherical coordinates, with the origin representing the adapting field; stimulus modulations are represented by the azimuth for the angle in the equiluminant plane, elevation for the projection onto the luminance axis, and stimulus strength being represented by the radial coordinate.

field methods Indirect psychophysical methods in which a test chromaticity is fixed, but an auxiliary stimulus such as masking noise is varied to determine the spectral sensitivity of the mechanism detecting the test.

first-site adaptation See cone-specific adaptation.

higher-order mechanism A chromatic mechanism tuned to an intermediate color direction, in-between the directions of the cardinal or classical mechanisms.

labeled line The idea, going back to Müller's Law of Specific Nerve Energies, that the activity of a mechanism is labeled such that its quality (e.g., red versus green) can be identified.

mechanism vector A triplet of three numbers that specify the relative amounts of L-, M-, and S-cone signals that are combined within a linear chromatic mechanism. The three weights may be all of the same sign (a nonopponent mechanism) or one or two may be negative (a cone opponent mechanism). The vector points in the direction of maximum responsivity in cone excitation or cone contrast space.

null plane The plane that goes through the origin of cone excitation or cone contrast space and contains stimuli that have no effect upon a linear chromatic mechanism. For a linear, bipolar mechanism these are the only stimuli to which the mechanism does not respond. For a unipolar mechanism the null plane is the boundary of the half of cone space to which the mechanism does not respond.

off-axis looking When multiple chromatic mechanisms have overlapping sensitivities in color space, a mechanism that is not tuned exactly to the test color direction (and is thus off-axis) may have the highest signal-to-noise ratio and therefore determine performance. Analogous to off-frequency listening in hearing.

second-site desensitization Adaptation that occurs at the output of a chromatic mechanism, and so acts upon a combined signal from more than one cone class.

test methods Psychophysical methods in which the chromaticity of a test is varied and spectral sensitivity is measured directly.

2.07.1 Introduction

Color vision begins with the encoding of light by the three classes of cone photoreceptor. In the modern approach to the study of chromatic detection and discrimination, the major thrust is to understand what computations are performed by the remainder of the visual system on the signals generated by the cones. Starting no later than the bipolar cells (Dacey, D. *et al.*, 2000), signals may be recombined so that they resemble a subtraction of the signals from different cone classes. By the late 1970s the picture that had emerged (Lennie, P. and D'Zmura, M., 1988) is that, at least by the time the signals reach the lateral geniculate nucleus (LGN), these cone-opponent signals are carried by three pathways or mechanisms: one opponent mechanism signaling a red–green difference, another opponent mechanism for a blue–yellow difference, and a third that carries a summed signal representing achromatic or brightness information. There were good reasons to accept this view: opponent computations like these create efficient representations of color (Buchsbaum, G. and Gottschalk, A., 1983), would help the visual system distinguish changes in surface materials from shadow boundaries (Rubin, J. M. and Richards, W. A., 1988), can explain much data from chromatic detection and discrimination experiments (Boynton, R. M., 1979), and also seemed to be consistent with phenomenological and psychophysical studies of color appearance (Hurvich, L. M. and Jameson, D., 1957), which can be described along color opponent red–green, blue–yellow, and bright-dark dimensions.

However, difficulties in describing both chromatic detection and color appearance within a single framework have led more recent theorists to propose a recoding of lower-level mechanisms suitable for detection to higher-level ones suitable for color

appearance (e.g., Guth, S. L., 1991; De Valois, R. L. and De Valois, K., 1993). The present treatment focuses on detection and discrimination, but even here complications – reviewed below – have arisen (Krauskopf, J. *et al.*, 1986a; Krauskopf, J., 1999). Over the past 20 years the textbook picture of three opponent detection mechanisms has been shown to be incorrect in many of its aspects. Consensus on a computable alternative theory has not yet emerged.

2.07.2 Definitions and Representations

2.07.2.1 Cone Signals and Spaces

To begin to understand how cone signals are transformed by the brain to serve color discrimination, one must first usefully represent the photoreceptor signals that are produced by visual stimuli. A representation employed in both psychophysics and physiology is that of cone excitations: lights are denoted by three numbers that are proportional to the quantal (or energy) catch rates in L-, M-, and S-cones. To represent test modulations above and below an adapting background field, the three excitations created by the adapting field (L_a, M_a, S_a) are subtracted from the excitations created by the test modulation to make local cone excitation coordinates ($\Delta L = L_{test}$-L_a, $\Delta M = M_{test}$-M_a, $\Delta S = S_{test}$-S_a). The influential DKL color space used by Derrington A. M. *et al.* (1984) is a linear transformation of these three coordinate axes, so that they no longer lie along the cone excitation directions but are along ΔL-ΔM, ΔS, and luminance axes (see Section 35.4.3.1). Spherical coordinates are often used, with the azimuth specifying the angle in the equiluminant plane (axes ΔL-ΔM, ΔS) and elevation specifying the projection onto the luminance axis. Because the axes of cone excitation space are scaled arbitrarily with respect to each other, many psychophysicists normalize the units along the axes to threshold values in order to define angles and distances.

An alternative to using cone excitations is to use cone contrasts, created by dividing the local cone excitation coordinates (e.g., ΔL) by the cone excitation produced by the adapting field (e.g., $\Delta L/L_a$ or simply $\Delta L/L$). By dividing out the background, cone contrasts approximately account for adaptation within the cones and within pathways before different cone signals are combined (Normann, R. A. and Perlman, I., 1979; Valeton, J. M., 1983; Valeton, J. M. and van Norren, D., 1983; MacLeod, D. I. A. *et al.*, 1992; MacLeod, D. I. A. and He, S., 1993). Accounting for first-site, cone-specific adaptation regularizes some data (see below) and helps to focus attention on neural computations that occur later in the system. Cone contrasts are dimensionless, and need not be further normalized.

2.07.2.2 Psychophysical Color Mechanisms

The nature and number of psychophysical color mechanisms is now in much dispute, as summarized below. One reason for this disagreement may be the lack of clear definitions of what is meant by the term mechanism. Explicit definition of the mechanism concept is particularly important when comparing psychophysics and physiology. At some level, a mechanism must be a neuron, but a neuron need not be a mechanism.

A chromatic detection mechanism is here defined as a fixed (relative) combination of cone signals which is correlated with the observer's behavior in detection and discrimination experiments. Mechanisms are stochastically independent at threshold. There is no need to require mechanisms to be orthogonal in any particular color space. The signals are combined in the mechanism postreceptorally, meaning that first-site, cone-specific adaptation has already occurred. This cone-specific adaptation is approximated by use of cone contrasts here, but other models of that adaptation could easily be substituted. Manipulations such as masking or habituation, or facilitation due to pedestals or edges (Eskew, R. T., 1989; Cole, G. R. *et al.*, 1990; Eskew, R. T. *et al.*, 1991; Gowdy, P. D. *et al.*, 1999b), which act at the mechanism output, change overall sensitivity but not chromatic tuning.

Two additional assumed properties of mechanisms make strong predictions about chromatic discrimination, thereby making the definition of mechanism more specific and testable. First, univariance implies that when two stimuli are detected by one and only one mechanism, there is some relative intensity at which the two stimuli cannot be discriminated from one another. Second, the labeled line assumption (Graham, N. V. S., 1989; Watson, A. B. and Robson, J. G., 1981) implies that when two stimuli are detected by different mechanisms, they must be discriminable from one another at all relative intensities. These discrimination assumptions have important implications. For example, since red and green stimuli, and S-increment and S-decrement

stimuli, can be discriminated from one another at detection threshold, (Krauskopf, J. *et al.*, 1986a; Mullen, K. T. and Kulikowski, J. J., 1990; Eskew, R. T. *et al.*, 2001), these stimuli are detected by different mechanisms, by definition. While the cone inputs may act antagonistically within the mechanism (they may be cone-opponent), the mechanism cannot be color-opponent in the traditional sense, because qualitatively different outputs must be associated with different mechanisms, according to these two assumptions. Although there are cells at early levels of the visual system that have bipolar responses, the responses of later cells that are the substrate for psychophysical mechanisms must be rectified in some way. Empirical evidence in support of the unipolar nature of psychophysical chromatic mechanisms is summarized below.

Consistent with the behavior of many cells in the LGN (Derrington, A. M. *et al.*, 1984), chromatic mechanisms are often modeled as quasi-linear combinations of cone signals, as shown in Figure 1. For example, for a green mechanism G,

$$G = \gamma P\left(w_L\frac{\Delta L}{L} + w_M\frac{\Delta M}{M} + w_S\frac{\Delta S}{S}\right) + N(0,\sigma)$$
$$= \gamma P(\mathbf{w}_G \cdot \mathbf{v}) + N(0,\sigma) \quad [1]$$

where

$$\mathbf{w}_G = (w_L w_M w_S), \quad \mathbf{v} = \begin{pmatrix} \Delta L/L \\ \Delta M/M \\ \Delta S/S \end{pmatrix}$$

and

$$P(x) = \begin{cases} x & x > 0 \\ 0 & x \le 0 \end{cases}$$

G is the number representing the mechanism response (crudely, an amount of greenness); $\mathbf{v}$ represents the stimulus by the vector of cone contrasts it produces; $\mathbf{w_G}$ is a unit-length vector of weights, each of which might be positive or negative; and γ is a positive number representing the gain of the mechanism. P is a half-wave rectification function (see below) that restricts the response to a single polarity; this nonlinearity is not present in traditional models, but the mechanism definition above and data summarized below require it. N refers to the probability density of a stochastic process, with zero mean and standard deviation σ, that is added to the mechanism in order to model all of the noise sources that corrupt its signal, viz., quantum light fluctuations, neural noises in cone-independent pathways, and neural noises at stages after cone signals have been combined.

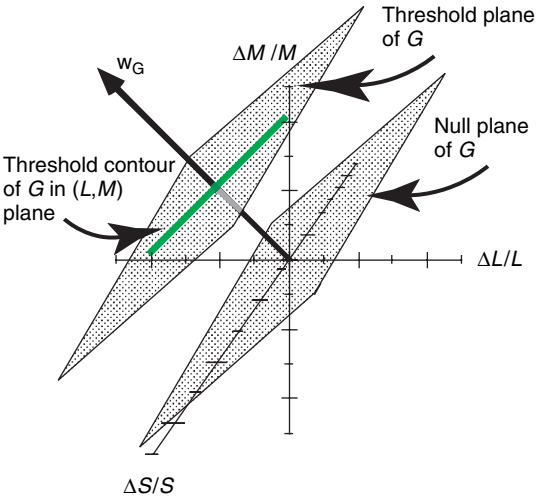

Figure 1 The mechanism vector $\mathbf{w_G}$ (straight arrow) for the G mechanism depicted in three-dimensional cone contrast space. The plane through the origin is the null plane; all stimuli in that plane, and all stimuli on the side of that plane opposite the mechanism vector, produce no response in the mechanism. The threshold plane contains all the stimuli producing a threshold-level response; the intersection of the threshold plane with the L,M plane of cone contrast space is the detection contour shown by the thick green line. Adapted from Eskew R. T., Jr., McLellan J. S., and Giulianini F. 1999. Chromatic Detection and Discrimination. In: Color Vision: from Genes to Perception (*eds*. K. Gegenfurtner and L. T. Sharpe), pp. 345–368. Cambridge University Press, figure 18.2, with permission.

The vector of weights $\mathbf{w}_G$ is the mechanism vector, with components that may be interpreted in signal/noise or d' units (Eskew, R. T. *et al.*, 1999). The mechanism vector points in the direction of maximum responsivity in cone contrast space. The response of this hypothetical half-wave linear mechanism (Giulianini, F. and Eskew, R. T., 2007) to any stimulus vector $\mathbf{v}$ is proportional to the projection of $\mathbf{v}$ onto the mechanism vector, in half of the color space, and zero in the other half (due to the rectification function, P). The linearity implies that stimuli that produce a constant response lie in planes in three-dimensional cone contrast space, or in lines in two-dimensional space, that are at right angles to the mechanism vector, since those regions have a constant projection onto the mechanism vector (Figures 1 and 2). A linear mechanism has a null plane that divides its two response polarities

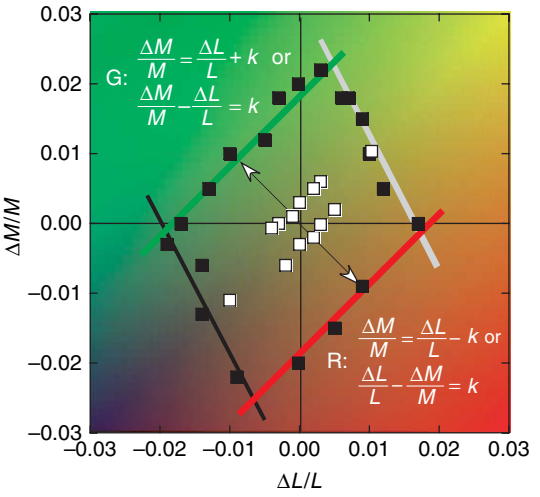

Figure 2 A detection contour measured in the (L,M) plane. The background color gradient roughly suggests the color of the test at that point in the plane. The tests were Gaussian blobs, flashed for 200 ms. The open symbols show unmasked detection, with typical long flanks of slope 1. Flickering random colored rings were superimposed over the test region for the measurements represented by the filled symbols; this noise color direction is indicated by the double-headed arrow. The double arrow also represents the G and R mechanism vectors. The noise shifts the G and R detection contours outward, without changing their shapes. Sensitivity to the 45° and 225° tests is unchanged, because these are detected by I and D which are largely unaffected by this noise. Adapted from Giulianini F. and Eskew R. T., Jr. 1998. Chromatic masking in the (ΔL/L, ΔM/M) plane of cone-contrast space reveals only two detection mechanisms. Vis. Res. 38, 3913–3926, Figure 3a, with permission.

(Derrington, A. M. *et al.*, 1984); half-wave linear mechanisms have a null volume bounded by this plane. Explicitly including rectification in the mechanism definition pushes the physiological substrate of the mechanism back into the cortex, where cells responses are rectified (De Valois, R. L. and De Valois, K., 1993) – and where that substrate is surely to be found, rather than in retina or LGN. It is worth noting that from a computational perspective, rectification can improve contrast coding in noisy neurons (von der Twer, T. and MacLeod, D. I. A., 2001).

2.07.3 Methods

Two classes of procedures, with a venerable history (Stiles, W. S., 1978), have been widely used to study detection mechanisms. In test methods, weak stimuli of various chromaticities are presented, without significantly altering the adapting state of the system, and sensitivity to the tests is measured. Field methods involve a fixed test stimulus, with steady or habituating-flicker fields, or added visual noise, used to alter the state of the system; the goal is to use changes in test threshold as a marker for sensitivity to the field stimuli.

A useful way to define stimulus strengths, including thresholds, is the vector length of a stimulus in cone contrast space, $|v| = \sqrt{(\Delta L/L)^2 + (\Delta M/M)^2 + (\Delta S/S)^2}$. This is the natural metric to use to characterize a linear (or half-wave linear) mechanism, and a measure based upon squared vector length, cone contrast energy (Chaparro, A. *et al.*, 1993) is especially useful for comparing mechanisms. Other measures are useful for this purpose too, particularly those based upon models of ideal chromatic observers (see Geisler, W. S., 1989; Sekiguchi, N. *et al.*, 1993; Brainard, D. H., 1996). It is not generally possible to compare mechanism sensitivities using cone excitation values, due to their arbitrary scaling.

2.07.4 Chromatic Mechanisms

2.07.4.1 Cardinal Mechanisms

The first six mechanisms reviewed below, arranged in three opposing pairs, are often referred to as cardinal mechanisms (Krauskopf, J. *et al.*, 1982a). This naming scheme refers to mechanisms, not by the color directions that best stimulate them, but by the color directions that isolate them (Knoblauch, K., 1995; Eskew, R. T. *et al.*, 1999) – that is, the cone modulations that would leave the other mechanisms unstimulated. Krauskopf J. *et al.* (1982) argued that these were: (1) an L–M axis where L- and M-cone excitation is exchanged at equal luminance and equal S-cone excitation; (2) an S-cone axis where S cones are modulated at equal luminance and unchanging |L–M|; and (3) a luminance axis. However, even ignoring the issues raised by studies of higher order color mechanisms (see Section 35.4.5), there are several problems with this model. First, the use of the S-cone axis to designate a mechanism may lead the unwary to believe, incorrectly, that this mechanism gets no input from L and M cones (the correct implication would be that the *other* mechanisms get no S-cone input). Second, there may in fact be a small S-cone input to the red and green detection mechanisms (see Section 35.4.2) contrary to the cardinal axis scheme. Third, it is now clear that the achromatic flicker mechanism gets L−M as well as S-cone inputs (see Section 35.4.4), also contrary to this scheme. Finally, as discussed below, psychophysical

mechanisms are unipolar (red rather than red/green). To avoid confusion, the term classical rather than cardinal will be used here for the unipolar R, G, B, Y, I, and D mechanisms (see next sections).

2.07.4.2 R and G Mechanisms

The best understood chromatic detection mechanisms receive oppositely signed inputs from L and M cones, are very sensitive to low- and medium-temporal and spatial frequencies, and generate percepts of orangey–red and bluish–green at and near threshold. Following convention, these mechanisms will be referred to as R and G, for red and green, although the percepts they create are certainly not unique hues (De Valois, R. L. and De Valois, K., 1993; De Valois, R. L. *et al.*, 1997; Wuerger, S. M. *et al.*, 2005). There is some evidence, collected using test methods, that one or both of these mechanisms receive a very small S-cone input (Boynton, R. M. *et al.*, 1983; Eskew, R. T. and Kortick, P. M., 1994; Stromeyer, C. F. *et al.*, 1998), and some evidence, collected using field methods, against that input (Krauskopf, J. *et al.*, 1982; Mollon, J. D. and Cavonius, C. R., 1987; Stromeyer, C. F. and Lee, J., 1988). It may be that a sensitive minority of relevant cells receive S-cone input (e.g., Derrington, A. M. *et al.*, 1984), but these cells are too desensitized by S-cone habituation or masking to contribute in the field procedures, leaving the cells without S-cone input to determine sensitivity; test methods would tap these sensitive cells and show an S-cone input (Stromeyer, C. F. and Lee, J., 1988). If so, this would imply multiple R and G mechanisms with very similar spectral tuning, since the S-cone weight is small at best.

R and G have been shown to be remarkably linear combinations of L- and M-cone contrasts using both test and field methods. The high sensitivities of R and G make it easy to isolate them with weak test stimuli in the (L, M) chromatic plane, and their threshold contours are remarkably straight (see Figures 2 and 3). This linearity is not only seen with very weak

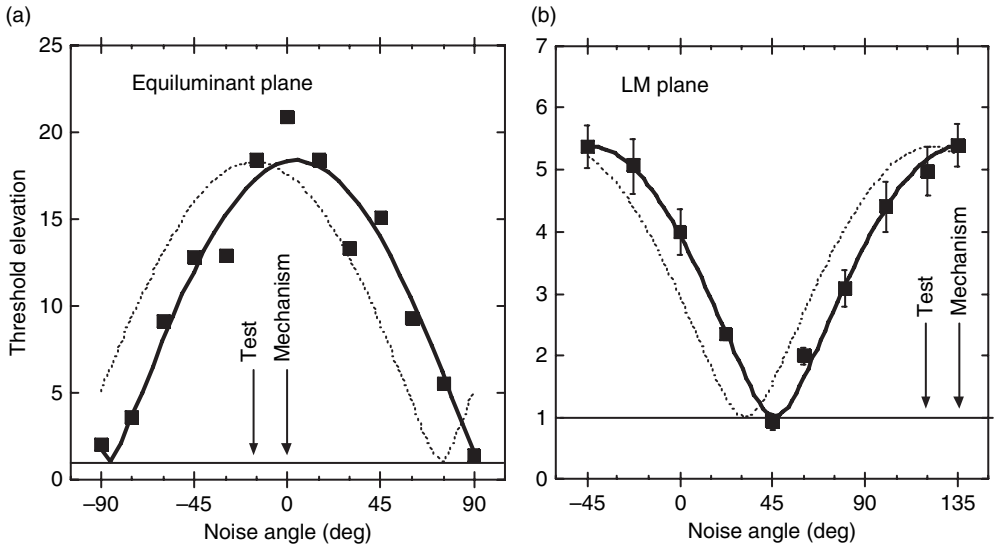

Figure 3 Threshold elevations plotted against the color angle of the masking noise in two different planes of cone contrast space, compared to the direction pointed to by the mechanism vectors $\mathbf{w_R}$ and $\mathbf{w_G}$ in these planes. (a) The test was a 1 cycle per degree equiluminant grating, with equal and opposite contrasts, at color directions of –16° and 164°. Only half of the symmetric data are shown. In this plane, the R and G mechanism directions are 0° and 180°, respectively. Replotted from Figure 4 of Sankeralli M. J. and Mullen K. T. 1997. Postreceptoral chromatic detection mechanisms revealed by noise masking in three-dimensional cone contrast space. J. Opt. Soc. Am. A 14, 2633–2646, with permission. Observer MJS. (b) The test was a green, equiluminant Gaussian blob (120° color direction). In this plane $\mathbf{w_G}$ points in the 135° direction, where the L and M contrasts are of equal magnitude and opposite sign. Adapted from Figure 4 of Giulianini, F. and Eskew, R. T., Jr. 1998. Chromatic masking in the (ΔL/L, ΔM/M) plane of cone-contrast space reveals only two detection mechanisms. Vis. Res. 38, 3913–3926, with permission. Observer F6. In both (a) and (b), the thick curve represents the best fit of $\sqrt{1+q\mathrm{Cos}^2(\alpha-\alpha_0)}$ (see eqn [2]). The dotted curve shows the same function shifted laterally to make the peak coincide with the test, illustrating that masking is aligned with the R and/or G mechanism directions, not the test direction. For both (a) and (b), the function applied in the original papers differs slightly from the correct one shown here.

signals; the contours remain straight (and of unity slope in the L,M plane) even when the use of noise (Giulianini, F. and Eskew, R. T., 1998; Stromeyer, C. F. *et al.*, 1999), chromatic adaptation (Chaparro, A. *et al.*, 1995), or tiny (Chaparro, A. *et al.*, 1994) or very brief (Eskew, R. T. *et al.*, 1994) test spots raises thresholds substantially. Giulianini F. and Eskew R. T. (2007) demonstrated linearity in G even when noise raised threshold by 20-fold (in one observer).

The mechanism vector for R is very close to $\mathbf{w}_R = (1, -1, 0)/\sqrt{2}$ (normalized to unit length) and, for G, $\mathbf{w}_G = -\mathbf{w}_R$, neglecting the possible small S-cone input. The equal and opposite L and M weights in both R and G mean that at threshold, the size of the difference between the L and M-cone signals $\left|\frac{\Delta L}{L} - \frac{\Delta M}{M}\right|$ is constant (Figures 2 and 3). Individual differences (in color normal observers) in these weights are very small (reviewed in Eskew, R. T. *et al.*, 1999). Thus, although observers differ widely in the relative numbers of L and M cones in their retinas (Hofer, H., *et al.*, 2005), these numbers are apparently not an important determinant of the strength of cone contrast inputs to R and G (except, of course, near the limit of protanopia or deuteranopia; see Chapter Spectral Sensitivity).

The symmetry of cone weights of R and G means their threshold planes or lines are parallel (Figure 2) and therefore no light can stimulate both of them; taken as a pair, these two cone-opponent mechanisms act very much like a color-opponent bipolar linear mechanism, with a null plane (where neither responds) that contains the equichromatic axis (the axis of lights with the same chromaticity as the adapting field). However, habituating to sawtooth modulations of chromaticity can selectively elevate thresholds for reddish or greenish stimuli (Krauskopf, J. *et al.*, 1986a; Krauskopf, J. and Zaidi, Q., 1986). Sankeralli M. J. and Mullen K. T. (2001) used unipolar tests and quick flashes of unipolar (e.g., red or green) noise and showed that masking was almost entirely restricted to the cases where the test and noise had the same polarity. These findings are consistent with other results that R and G are separate mechanisms in the fovea at threshold (Gowdy, P. D. *et al.*, 1999a; 1999b), as well as with models such as that of De Valois R. L. and De Valois K. (1993). This empirical evidence buttresses the use of the univariance and labeled line assumptions in the definition of mechanism (Section 35.2.2). The evidence outlined above indicates that R and G are linear except for this rectification.

A field method may be used to study this linearity, by adding dynamic noise of various chromaticities to a white background field. The theory of noise masking (Burgess, A. and Barlow, H. B., 1983; Legge, G. E. *et al.*, 1987; Pelli, D. G., 1990), in which test contrast energy is related to noise power, leads to the expectation that the squared threshold elevation is linear with the squared-cosine of the angle between the noise vector at α and the mechanism vector $\mathbf{w}$ at α_0,

$$(c/c_0)^2 = 1 + q'(\mathbf{r}\cdot\mathbf{w})^2 = 1 + q\,\mathrm{Cos}^2(\alpha - \alpha_0) \qquad [2]$$

where $\mathbf{r}$ is the vector of noise, c is the threshold with noise and c_0 without it, and q and q' are constants that account for stimulus parameters as well as the rectification in eqn [1]. The chromatic masking bandwidth (half-width at half-height) of Eqn. (2) is 45°, or about 56.5° if the square root is taken of both sides (not the 60° of a cosine). Figure 3 shows that threshold elevations for stimuli detected by R or G follow this relationship closely (Sankeralli, M. J. and Mullen, K. T., 1997; Giulianini, F. and Eskew, R. T., 1998), consistent with linear detection. Note that the maximum masking is not obtained at the test direction; rather, the maximum is at the mechanism direction α_0 (the direction that $\mathbf{w}$ points) in both of these planes of color space (see section 35.4.5).

Figure 4 shows R and G thresholds collected on green, red/green–neutral (yellow), and deep red adapting fields (Chaparro, A. *et al.*, 1995). The detection contours have unit slope in all conditions, indicating that the use of cone contrasts has adequately accounted for different first-site adaptations produced by the three fields. In comparison, the same data plotted in local cone excitation coordinates (right) show substantial variation in slope with adapting chromaticity. Because the pairs of cone contrast contours are parallel to the equichromatic axis (at 45°) on all three field colors, neither mechanism will respond to radiance modulations (such as, approximately, shadows), regardless of the prevailing chromatic conditions. Both the R and G thresholds are higher on the red fields, indicating postreceptoral, second-site desensitization of the combined cone signal. This desensitization means the criterion signal k must be larger on the red field for both G and R; that both mechanisms are desensitized suggests the locus of second-site desensitization is prior to the rectification that splits early bipolar signals into unipolar mechanisms.

R and G are more sensitive than achromatic mechanisms (and, presumably, B and Y; see below),

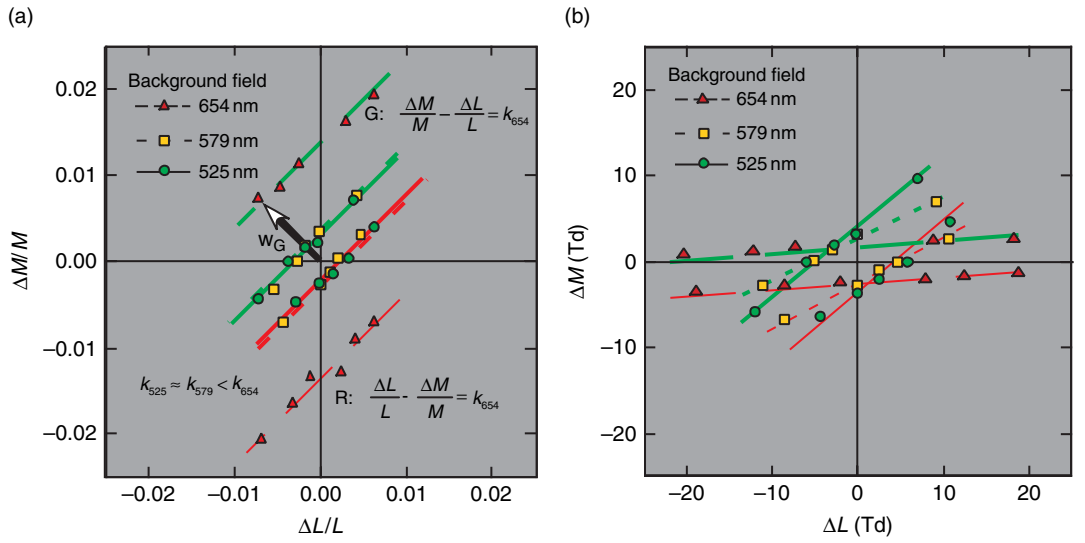

Figure 4 (a) Thresholds measured on three chromatic adapting fields (525, 579, and 654 nm), plotted in cone contrast space. The upper lines represent the G mechanism; the lower lines, R. On the red field, the magnitude of the threshold-level response (k) is largest, but the contour slope is 1.0 in all cases. The heavy arrow depicts the G mechanism vector, at a polar angle of 135° where the L and M contrast weights are of equal magnitude and opposite sign. (b) The same data as in (a) but plotted in local cone excitation coordinates. Without using the contrast variables to account for first-site, cone-specific adaptation, the detection contour slopes vary with field color. Adapted from Chaparro A., Stromeyer C. F., 3rd, Chen G., and Kronauer R. E. 1995. Human cones appear to adapt at low light levels: measurements on the red–green detection mechanism. Vis. Res. 35, 3103–3118, figures 2 and 4, with permission.

even at the shortest flash durations (Eskew, R. T. *et al.*, 1994) and for very tiny spots (Chaparro, A. *et al.*, 1994). Even when R or G is compared with the increment achromatic mechanism using spot sizes and durations that are optimal for each mechanism, R/G is about seven times more sensitive in contrast energy terms (Chaparro, A. *et al.*, 1993). In cone contrast space, the vast majority of the chromatic volume will be detected by R or G except at high temporal frequencies (>15 Hz), for reasonably bright adapting conditions (Stromeyer, C. F. *et al.*, 1987).

The sensitivity of R and G is highest in the central fovea and falls off rapidly with eccentricity (Mullen, K. T., 1991; Stromeyer, C. F. *et al.*, 1992; Mullen, K. T. and Kingdom, F. A., 2002). Dating at least back to Abney W. d. W. (1897), data has suggested that sensitivity to green falls off more rapidly with eccentricity than other colors, including red (for historical reviews, see Parsons, J. H., 1915; Boring, E. G., 1942). More recent studies confirm this peripheral asymmetry (Moreland, J. D. and Cruz, A., 1959; Conners, M. M. and Kelsey, P. A., 1961; Abramov, I. *et al.*, 1991). It is now clear that the loss of sensitivity to green is postreceptoral: there are losses in sensitivity to L-cone decrements as well as M-cone increments (and their combinations), compared to L-cone increments and M-cone decrements (and their combinations; Stromeyer, C. F. *et al.*, 1992; Newton, J. R. and Eskew, R. T., 2003; Sakurai, M. and Mullen, K. T., 2006). Whether (Hagstrom, S. A. *et al.*, 1998) or not (Deeb, S. S. *et al.*, 2000) there is variation in the relative L- and M-cone number with eccentricity is not relevant. The site of the asymmetry is most naturally attributable to double-opponent cells in the cortex (Hubel, D. H. and Wiesel, T. N., 1968; Gouras, P., 1974; Michael, C. R., 1978; Livingstone, M. S. and Hubel, D. H., 1984; Tootell, R. B. *et al.*, 1988; Gegenfurtner, K. R., 2003; Lennie, P. and Movshon, J. A., 2005), which have the type of correlation between cone type and increment/decrement polarity that seems called for, but since these cells are often studied with red–green gratings and many of them respond to equichromatic stimuli as well as red–green ones (e.g., Johnson, E. N. *et al.*, 2001) the actual locus of this asymmetry is unknown.

2.07.4.3 B and Y Mechanisms

The central panel of Figure 5 shows detection data collected in the equiluminant plane with a Gabor patch test (which, since it contains tests of two symmetric polarities, produces a set of symmetric

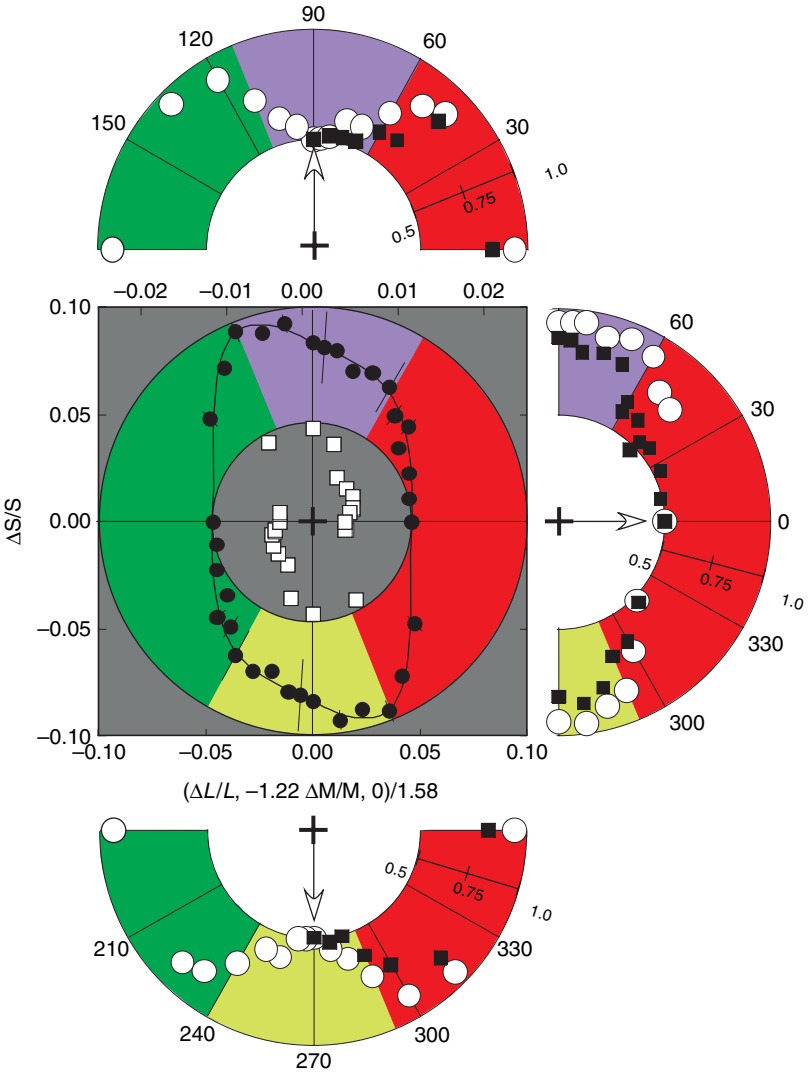

Figure 5 The center square panel shows detection thresholds for Gabor patches with (filled symbols) or without (open symbols) red/green masking noise (0°/180° color direction). Note that the horizontal scale is expanded for the no-noise thresholds represented by the open symbols, as shown on the top axis. The weighting constants on the L-M contrast axis result from using unit-length basis vectors in the equiluminant plane. Data are symmetric about the origin due to the symmetric stimuli. The solid black line fitted to the masked thresholds represents probability summation among four symmetric unipolar linear mechanisms. The three arcs are polar plots, with the angular coordinate referring to the same stimuli, at the same angles, as in the detection data. The radial coordinate gives the discriminability (0.5–1.0) of the given test color angle with the standard color angle indicated by the arrow. Solid symbols are data, open symbols are predictions of a Bayesian classifier model that takes the outputs of the four mechanisms fitted to the detection data as its inputs. All the parameter fitting was done in estimating the detection model; the discrimination predictions are made with no free parameters. Colored regions indicate bands of poorly discriminated stimuli, and are redrawn on the detection plot for comparison. Adapted from Figure 4 of Eskew, R. T., Jr., Newton, J. R., and Giulianini, F. 2001. Chromatic detection and discrimination analyzed by a Bayesian classifier. Vis. Res. 41, 893–909, with permission, observer JRN; the greenish indiscriminability region was taken from model fit and data from other observers.

thresholds). The open symbols make up a pure test method detection contour. Thresholds along the vertical, S cone, axis are about 10 times higher than those along the horizontal, red/green axis (top horizontal axis scale), consistent with the long-established insensitivity of S-cone detection (Stiles, W. S., 1949). This insensitivity means that it is very difficult to use direct, test methods alone to isolate and study the B and Y mechanisms. The filled symbols show a repetition of the experiment with red/green masking

noise added (along the horizontal axis direction), which expands the contour horizontally (and, to a lesser extent, vertically – S-cone detection here is not independent of modulations along the R/G direction). The smooth contour is a fit of a probability summation model based upon symmetric R and G, and B and Y mechanisms; the long straight segments represent isolated mechanisms (B, R, Y, and G going clockwise from top). Even after R and G have been desensitized by the noise, they still dominate the detection contour. In this particular set of data it appears that the detection contour at top and bottom, representing B and Y, is reasonably linear over its limited extent; in other data it is more difficult to tell (Eskew, R. T. *et al.*, 2001).

Sankeralli M. J. and Mullen K. T. (1997) added static one-dimensional noise to raise thresholds of S-cone gratings. The threshold elevations were roughly consistent with the (linear) cosine model. Sankeralli M. J. and Mullen K. T. found evidence that the L- and M-cone inputs to the mechanisms responsible for S-cone detection had roughly equal magnitudes and were both opposite in sign to the S-cone weight. Mullen K. T. and Kingdom F. A. (2002) found sensitivity to S-cone gratings to decrease less sharply with eccentricity than to R/G gratings.

However, these studies used S-cone gratings with both incremental and decremental components. Like R and G, S increments can be masked independently of S decrements and vice versa (Sankeralli, M. J. and Mullen, K. T., 2001), but whereas (in the fovea) R and G are remarkably symmetric (opposite cone weights, identical sensitivity), this is not so for S-cone detection. Thresholds may be higher for S increment than S decrement spots (Vassilev, A. *et al.*, 2003), transient adapting flashes and pedestal masks raise S increment more than S decrement thresholds (Shapiro, A. G. and Zaidi, Q., 1992; Zaidi, Q. *et al.*, 1992; Vingrys, A. J. and Mahon, L. E., 1998), and also the long-wave inputs differ as a function of S-cone polarity (Shinomori, K. *et al.*, 1999; McLellan, J. S. and Eskew, R. T., 2000), meaning that – even if each were half-wave linear – their mechanism vectors (Figure 1) would not be opposite one another. McLellan J. S. and Eskew R. T. measured action spectra for transient tritanopia (Stiles, W. S., 1949; Pugh, E. N. and Mollon, J. D., 1979) using S increment and decrement tests. The function for S increment tests is shifted to longer-wavelengths, suggesting a relatively greater L-cone input to B than to Y. Both action spectra are too narrow to be any linear combination of L and M signals, consistent with results of Giulianini F. and Eskew R. T. (2007) who used a noise superposition test to show that both B and Y are nonlinear. Cortical cells with substantial S-cone inputs have been reported to be significantly nonlinear (Cottaris, N. P. and De Valois, R. L., 1998; Horwitz, G. D. *et al.*, 2005).

S-ON signals are carried in at least two distinctly different pathways, and S-OFF in at least one other (Dacey, D. M. and Lee, B. B., 1994; Klug, K. *et al.*, 2003; see review by Dacey, D. M. and Packer, O. S., 2003). Given these differences in anatomy it is not surprising that the L- and M-cone inputs that oppose S increment and S decrement signals would differ. Indeed, Solomon S. G. and Lennie P. (2005) have recently reported an asymmetry in L and M-cone opposition to S increments and decrements in LGN cells.

2.07.4.4 I and D Mechanisms

The letters I and D stand for increment and decrement. These mechanisms are thought to be isolated by cone modulations along the main diagonal of three-dimensional cone contrast space, the equichromatic direction, where the three cones are modulated in the same proportion to their background quantal catches. Together these mechanisms are usually called the luminance mechanism, but that term is avoided here because of the confusion it causes with photometric luminance, and to be parallel with the terms used for the other mechanisms above. There is little doubt that I and D are distinct mechanisms as defined above (Krauskopf, J., 1980; Krauskopf, J. *et al.*, 1982; Bowen, R. W. *et al.*, 1989; Tyler, C. W. *et al.*, 1992; Bowen, R. W. and Wilson, H. R., 1994; Bowen, R. W., 1997).

These mechanisms are of relatively low sensitivity except at high temporal frequencies, and they are therefore often studied using 12 Hz or faster flicker (or motion). Because flicker contains both incremental and decremental contrasts, it cannot be used psychophysically to study I and D separately, and the results, depending on conditions, might represent the more sensitive of I or D or some mixture of the two. Despite this important limitation, flicker experiments have made important contributions.

For example, it is now abundantly clear that I/D receives a spectrally opponent, L−M signal in addition to the additive L + M signal postulated in the textbook models (Lindsey, D. T. *et al.*, 1986; Swanson, W. H. *et al.*, 1987; Stromeyer, C. F. *et al.*, 1997; Stockman, A. and Plummer, D. J., 2005; Stockman, A. *et al.*, 2005), and analogously to the magnocellular

ganglion cells that are often hypothesized to underlie flicker detection (Smith, V. C. *et al.*, 1992; Lennie, P. *et al.*, 1993). In Stockman's model (Stockman, A. and Plummer, D. J., 2005; Stockman, A. *et al.*, 2005), fast L and fast M signals are combined with slow L and slow M signals. The slow, opponent inputs (sL and sM) and fast, nonopponent inputs (fL and fM) have relative magnitudes and temporal phases that depend upon the chromaticity to which the observer is adapted, so under some adapting conditions (e.g., high-intensity red fields) the slow inputs are of opposite sign to the fast ones and in other conditions (e.g., lower-intensity red fields) the slow inputs have the same signs as the fast ones. Direct comparisons show no phase shifts between L- and M-cone signals in R/G under the same conditions in which they are found in I/D (Stromeyer, C. F. *et al.*, 1997). Besides inducing phase shifts, chromatic adapting fields can cause suppression of signal amplitudes (Eisner, A. and MacLeod, D. I. A., 1981; Stromeyer, C. F. *et al.*, 1987; Tsujimura, S. *et al.*, 1999). In addition to these complicated L- and M-cone inputs, there is a slow S-cone input to I or D or both (Stockman, A. *et al.*, 1991). These extra inputs are not, in general, directly observable on chromatically neutral fields.

The luminance mechanism is generally believed to be a linear combination of cone signals, because photometric matches approximately obey Abney's Laws – i.e., they are additive (Wyszecki, G. and Stiles, W. S., 1982). Such tests have generally been performed only with relatively high flicker frequencies, and under conditions where the observer's state of adaptation changes with the wavelengths of the stimuli. However, flicker or motion thresholds taken under constant adaptation conditions also appear to result from linear cone combinations (Stromeyer, C. F. *et al.*, 1987; 1995), with most evidence obtained at higher temporal frequencies. When a fixed chromatic noise is used to help isolate I and D, detection contours for flashes in the L,M plane appear reasonably straight (Giulianini, F. and Eskew, R. T., 1998), over the very limited range of L/M ratios that can be studied with this test method. When Sankeralli M. J. and Mullen K. T. (1997) used a field method, by superimposing various noises on an achromatic grating, they described the threshold elevations with the cosine relationship (eqn [2]); however, in fact the fit to the data in the L,M plane of cone contrast space was much worse than the corresponding ones for R/G (e.g., Figure 3(a)), suggesting significant nonlinearities of cone combination in I/D.

Most of these studies used flicker or gratings, and since those results reflect some mixture of two mechanisms they do not bear on the symmetry of I and D. Moreover, nonlinearities might be hidden behind the envelope of the most-sensitive of the two mechanisms. The linearity of cone combinations in I and D, at least at low-temporal frequencies, is not well established.

2.07.4.5 Higher-Order Mechanisms

In an extremely influential paper, Krauskopf J. and colleagues (1986a) found evidence for what they termed higher-order color mechanisms, conceived of as recombinations of signals from the cardinal mechanisms, and tuned to intermediate color directions (such as orange or blue–green). The summary above has already indicated that, as Krauskopf J. and colleagues concluded 20 years ago, the textbook picture of three bipolar, linear mechanisms is incorrect. Although the pair of R and G mechanisms comes close to being such a mechanism (because of their linearity, symmetrical cone weights, and equal sensitivity), the other possible pairs are dissimilar from bipolar mechanisms.

Evidence for higher-order mechanisms has been obtained from studies of detection (Krauskopf, J. *et al.*, 1986a; Gegenfurtner, K., and Kiper, D., 1992; D'Zmura, M. and Knoblauch, K., 1998; Lindsey, D. T., and Brown, A. M., 2004), classification images (Bouet, R. and Knoblauch, K., 2004; Hansen, T. and Gegenfurtner, K. R., 2005), first-order discrimination (Krauskopf, J. *et al.*, 1986a; Krauskopf, J. and Gegenfurtner, K., 1992; Zaidi, Q. and Halevy, D., 1993; Li, A. and Lennie, P., 1997; Hansen, T. and Gegenfurtner, K. R., 2006), and second-order (texture) discrimination (Goda, N. and Fujii, M., 2001). Other tasks providing such evidence include visual search (D'Zmura, M., 1991; Monnier, P. and Nagy, A. L., 2001; Nagy, A. L. and Thomas, G., 2003), spatial alignment (McGraw, P. V. *et al.*, 2004; McKeefry, D. J. *et al.*, 2004), detection of Glass patterns (Wilson, J. A. and Switkes, E., 2005), motion coherence (Krauskopf, J. *et al.*, 1996), tilt aftereffect (Flanagan, P. *et al.*, 1990), and color appearance (Krauskopf, J. *et al.*, 1986b; Webster, M. A. and Mollon, J. D., 1991; 1994; Mizokami, Y. *et al.*, 2004). However, after 20 years of these and other studies, no higher-order mechanism has yet been isolated and characterized the way that R and G have been, and much is still unclear. The key issue, of course, is whether there are more than the six mechanisms described above, or whether

the unipolar, asymmetric, and nonlinear aspects of some of these mechanisms suffice to explain the results that have been attributed to additional mechanisms.

Using noise masking in the chromatic plane in which only L and M cones are modulated, Li A. and Lennie P. (1997) and Giulianini F. and Eskew R. T. (1998) found evidence for only four mechanisms (R, G, I, and D, in the present terminology). In particular, maximal masking was not generally obtained along a given stimulus (noise) direction, as might be expected if there were many different mechanisms, but rather along the mechanism directions of R and G (Figure 3); this result does not agree with Gegenfurtner K. and Kiper D.'s (1992) innovative early study. Stromeyer C. F. *et al.* (1999) offered a compelling alternative account of Gegenfurtner K. and Kiper D.'s results based upon spatial phase interactions between grating stimulus components, but recently Hansen T. and Gegenfurtner K. R. (2006) used a stimulus consisting of discrete checks (designed to minimize such interactions) and still obtained maximal masking in the test direction.

Most of the other experiments on higher-order mechanisms were conducted in an equiluminant plane, in an attempt to silence I and D. However, as noted above, the linearity of I/D is not well established, and if these mechanisms are nonlinear they may not be silent in any given plane. Furthermore, it is well established that these mechanisms receive a spectrally opponent signal (Stockman, A. *et al.*, 2005) at least under some conditions. Therefore it is not always clear whether one should compare results collected in the equiluminant plane against a model with four (R, G, B, and Y) or six (plus I and D) mechanisms. Another justification for using the equiluminant plane is that it includes the S-cone axis, and it is plausible that multiple, higher order mechanisms would get input from multiple, S-cone pathways (Dacey, D. M. and Packer, O. S., 2003).

How many mechanisms have been found in the equiluminant plane? In a detection experiment using noise masking of Gabor patches, Eskew R. T. *et al.* (2001), were able to account for detection contours using only four mechanisms (R, G, B, and Y), independent of the noise color direction: noises at four different color angles produced maximum masking at the classical R/G and B/Y directions, but not at intermediate noise directions (Figure 5, central panel, shows data from one noise condition). In addition, these authors used a discrimination procedure to test the model based upon these four mechanisms: pairs of threshold-level stimuli (in the presence of the noise), were presented in random order to the observer, who had to pick the designated standard color pairs (because these were Gabor patches, the discrimination was of a color at a particular spatial phase). The logic is based upon the two discrimination assumptions (see Section 35.3.2.2): if and only if the two stimuli are detected by the same mechanism will two threshold-level stimuli be indiscriminable. The three arcs in Figure 5 represent discrimination data (filled squares) and model predictions (open circles) in polar coordinates. Within each arc, the angular coordinate represents the angle of the stimulus (same angles as in the central panel of detection data), and the radial coordinate represents the proportion of tests that were discriminable from the standard. Three standards are shown (arrows). Consider the right-hand arc, with a standard stimulus represented along the 0°/180°, red–green horizontal axis. The observer was unable to discriminate this standard from tests lying between about 300° and 60°; these angles have been colored red. In contrast, tests lying above 60° (purple) or below 300° (yellow) were readily discriminable from the standard. Taken together with other data not shown here, the results of this experiment suggest only four spectral bands of indiscriminable stimuli.

These results are consistent with earlier work. Using monochromatic increment lights in the Rayleigh spectral region, Calkins D. J. *et al.* (1992) found only three bands of indiscriminable stimuli (detected by R, G, and I, presumably), up to 0.7 log units above threshold. At threshold, across the entire visible spectrum, Mullen K. T. and Kulikowski J. J. (1990) also found evidence for a limited number of indiscriminable spectral bands (four or five, with the fifth corresponding to violet and possibly indicating an S-cone input to R). Neither result is consistent with the existence of a large number of (labeled line) mechanisms.

The open circles in Figure 5 represent predicted discriminability based upon a Bayesian classifier that takes, as its input, the responses of R, G, B, and Y. Discrimination performance is generally, and unsurprisingly, slightly lower for the inefficient human than the efficient Bayesian classifier. However, Krauskopf J. *et al.* (1986a) interpreted a similarly sized discrepancy in discrimination performance as representing detection by multiple mechanisms, thus leading to imperfect discrimination (in essence, thresholds are lowered by probability summation among mechanisms but discrimination is made

more difficult). The size of the discrepancy needing explanation suggests the difficulty of settling this vexed issue.

D'Zmura M. and Knoblauch K. (1998) used two masking noise components, one aligned with the test color direction and the other perpendicular to it. These two noise components were summed to make a fanlike sector of noise, centered on the test color direction, which was varied in width by altering the amplitude of the orthogonal noise component. If the test were detected by a linear mechanism tuned to the test direction, the noise sector width would have no effect (because the orthogonal noise has no effect). Some of the four chosen test directions (e.g., orange) were selected to simultaneously stimulate two classical mechanisms, which would result in an increase in masking with increasing noise sector width. Yet the clear result was that the amount of masking was independent of sector width for all four test directions, which would be very difficult to explain with only classical mechanisms even if they are assumed to be nonlinear and asymmetric. D'Zmura and Knoblauch interpreted their findings to mean there must be a large number of linear mechanisms tuned to various directions.

Recently Hansen T. and Gegenfurtner K. R. (2006) used a field method in the equiluminant plane. With a single noise vector, maximal masking was obtained at each test direction rather than the expected classical mechanism direction (unlike Figure 3), consistent with detection by multiple mechanisms tuned to various directions, and the tuning function was narrower than the cosine predicted by linear cone combination. This nonlinearity was attributed to off-axis looking, shifting between multiple mechanisms that have overlapping sensitivities (see also D'Zmura, M. and Knoblauch, K., 1998). With noises consisting of two vectors that were symmetrically disposed about the test direction (to defeat off-axis looking), cosine (linear) tuning curves were obtained. In these conditions, however, maximal masking was not always obtained at the test direction.

On the one hand, off-axis looking between linear mechanisms may produce narrow, spuriously nonlinear tuning curves; on the other hand, the noise masking stimuli typically available for field method experiments in the equiluminant plane, which are sharply limited in contrast power, may produce spurious linearity due to weak inputs (Giulianini, F. and Eskew, R. T., 2007). The interplay of these two factors might account for some of the differences between studies on higher-order color mechanisms.

Krauskopf J. and Gegenfurtner K. (1992) measured pedestal discrimination contours, by presenting four 36 min. diameter disks around a central fixation spot, all on a 10° steady white adapting field. Three of the four disks had the same chromaticity, one of them was different, and the observer's task was to select that one (a four spatial alternative forced-choice task). In other words, three pedestal stimuli were presented along with a fourth stimulus that consisted of the (vector) sum of the pedestal plus a test; the discrimination of the odd disk is equivalent to detection of the test in the presence of a pedestal. Krauskopf J. and Gegenfurtner K. varied the chromaticity of the pedestal in the equiluminant plane. Data are shown in Figure 6.

Krauskopf J. and Gegenfurtner K. argued that if discrimination was based solely on mechanisms tuned to the cardinal axes (the axes of the graph), the discrimination contours should be oriented with their long axis parallel to the closest cardinal axis,

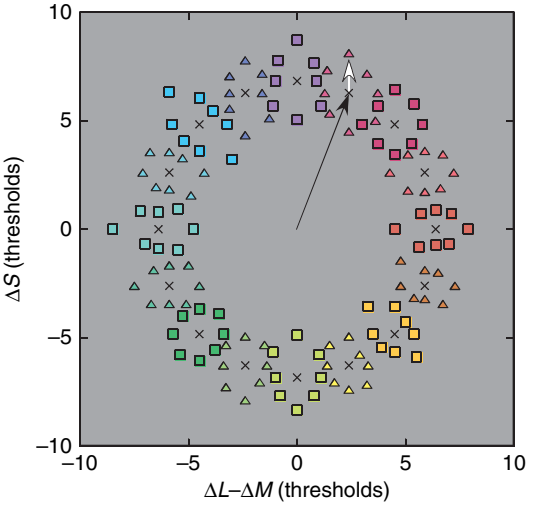

Figure 6 Pedestal discrimination thresholds. The center of the plot represents the white monitor background. Excursions along the two cardinal axes are represented along the horizontal and vertical axes, each scaled in units of the threshold for detection (with no pedestal). One pedestal vector is illustrated by the black arrow; to it is added an S-cone increment test (white arrow). The x represent the tips of all of the pedestal vectors; the distance to each symbol from the x represents the amount of test modulation required to discriminate test + pedestal from pedestal alone. Discriminations around each pedestal are coded with different shapes and colors for clarity; the color of each set of symbols very roughly represents the color of the pedestal alone. Adapted from Figure 14 of Krauskopf J. and Gegenfurtner K. 1992. Color discrimination and adaptation. Vis. Res. 32, 2165–2175, with permission.

because the pedestal masking would occur primarily in that direction. For the pedestals that are equidistant from the two axes (45°, 135°, 225°, and 315°) the contour should be roughly circular. In contrast, if there are higher-order mechanisms tuned to many directions in color space all the contours should be of similar shapes with their long axis pointed at the origin, since each pedestal would mask maximally and equally in its own color direction, the same logic as in some noise masking experiments discussed above. As Figure 6 shows, most of the sets of thresholds would be well described by the cardinal axes account, but two of the pedestals (at 135° and 315°) are more like the higher-order one.

Only a handful of studies have explicitly tried to estimate the number of higher-order mechanisms. Zaidi Q. and Halevy D.'s (1993) model of dynamic chromatic discrimination required more than four, and Goda N. and Fujii M.'s (2001) texture discrimination model required five or seven depending on observer. Hansen T. and Gegenfurtner K. R. (2006) tested models with four, eight, and 16 mechanisms and found that four mechanisms could not account for their results, and 16 provided a better fit than eight. However, Giulianini F. and Eskew R. T. (2007) showed that the same model failed to account for noise masking of S-cone increment or decrement tests in the three principal planes of cone contrast space.

In summary, a substantial number of studies have found evidence against the textbook model of three, bipolar, linear chromatic mechanisms. Some of these studies have provided evidence that there are more than the six, unipolar mechanisms reviewed above. None of these higher-order mechanisms has been isolated and characterized, and there is disagreement as to their number and nature. Partly the issue may be that different mechanisms come into play for different tasks, yet there is controversy even for the detection and simple discrimination tasks emphasized here.

2.07.5 Conclusions

Two detection mechanisms, R and G, have been very well characterized. The other four classical mechanisms (B, Y, I, and D) are less well understood. If there are higher-order detection mechanisms in addition to these six, it seems likely that these will cover some of the same chromatic territory that was attributed to B and Y above, as the peculiarities of S-cone pathways and performance suggest.

The cortical neurons that have been studied electrophysiologically undoubtedly have more diverse chromatic tuning than do LGN neurons (Gegenfurtner, K. R., 2003; Lennie, P. *et al*., 1990; Lennie, P. and Movshon, J. A., 2005), and this increased variability has often been taken to support the existence of higher-order psychophysical color mechanisms. However, given that no particular neuron can yet be identified with a color mechanism, and it is not even clear which cortical areas are most relevant, caution would seem to be called for. Until the psychophysics is better understood, it will be difficult to interpret the ever-increasing knowledge of the behavior of single visual neurons.

Since a large number of different lights – not to mention surfaces – can be discriminated in color, there must be different neurons at some level of the brain that are tuned to many different color directions, at least at the moment the discrimination is made. The question is only whether their behavior can be characterized as consistent with a well-defined psychophysical mechanism.

Acknowledgments

Thanks to Charles Stromeyer and Karl Gegenfurtner for providing the data in Figure 3 and 6, respectively. Preparation of this chapter was supported by NIH EY09712.

2.08.1 Specifying and Describing Color

Because of the importance of color measurement in the materials, printing, electronic imaging, and lighting industries, a large technical vocabulary has evolved based on international agreement. Recommendations of the Commission Internationale de l'Eclairage (CIE) concerning colorimetry and a color-appearance model are available in two technical reports (CIE, 2004a; 2004b). Colorimetric terms and formulas are introduced here only as they are needed, and the specification of color appearance with reference to proprietary color-order systems is not discussed (e.g., see Wyszecki, G. and Stiles, W. S., 1982; Hunt, R. W. G., 1998; Fairchild, M. D., 2005).

2.08.1.1 The Color Signal and Spectral Sampling

The light reflected from an illuminated scene or emitted by an electronic display system produces a stimulus to the human eye consisting of a distribution of spectral radiance $c(\lambda)$ over wavelength λ at each point in the field of view. For reflected light, this color signal $c(\lambda)$ (Buchsbaum, G. and Gottschalk, A., 1983) is

the wavelength-by-wavelength product of an illuminant spectrum $E(\lambda)$ and the spectral reflectance $R(\lambda)$ at each point in the scene; that is, $c(\lambda) = E(\lambda)R(\lambda)$, in suitable radiometric units. Figure 1, first column, shows the normalized spectrum $E_1(\lambda)$ of light from the sun (second row) illuminating a flower stamen with spectral reflectance $R_1(\lambda)$ (third row), giving the color signal $c_1(\lambda) = E_1(\lambda)R_1(\lambda)$ (fourth row).

The color signal, imaged onto the retina, is normally sampled by the long-, medium-, and short-wavelength-sensitive cone photoreceptors with spectral sensitivities $L(\lambda)$, $M(\lambda)$, and $S(\lambda)$, respectively (Figure 1, fifth row). The corresponding cone excitations l_1, m_1, and s_1, are obtained by integrating the product of $c_1(\lambda)$ with, in turn, $L(\lambda)$, $M(\lambda)$, and $S(\lambda)$ over wavelength λ.

If any two spectra, for example $c_2(\lambda)$ and $c_3(\lambda)$ in Figure 1 (second and third columns, fourth row), produce triplets (l_2, m_2, s_2) and (l_3, m_3, s_3) of excitations at a point that are the same, then they are visually indistinguishable, for after absorption all information about their spectral origins is lost (Naka, K. I. and Rushton, W. A. H., 1966). But as is evident here, identical triplets do not imply identical color signals: $c_2(\lambda)$ and $c_3(\lambda)$ are different functions of λ. In general, color signals need more than three numbers to specify them, experimentally about eight with natural scenes (Nascimento, S. M. C. *et al.*, 2005b). This ambiguity – of different spectra producing the same cone excitations, and therefore the same color information – is known as metamerism (Wyszecki, G. and Stiles, W. S., 1982; Hunt, R. W. G., 1998). Metamerism can arise from differences in illuminant spectra or reflectance spectra or other viewing factors, and it sets a limit, even under constant viewing conditions, on how well color can be used to represent the spectral properties of surfaces.

2.08.1.2 Tristimulus Values

With just three classes of cones in the normal eye, the colors of stimuli could be specified by triplets of cone excitations, as in Figure 1, but for historical reasons, the established system of colorimetry is instead based on color-matching functions $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$, which represent the amounts, sometimes negative, of three monochromatic, primary lights needed to match a monochromatic light of constant radiant power at each wavelength λ (Wright, W. D., 1928–1929; Guild, J., 1931). For computational convenience, these color-matching functions – standardized internationally in 1931 by the CIE – were transformed to a new set of functions $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ with non-negative values and with $\bar{y}(\lambda)$ equated to $V(\lambda)$, the daylight luminance sensitivity of the eye. An arbitrary color signal $c(\lambda)$ in this system is specified by a triplet of tristimulus values X, Y, and Z, obtained by integrating the product of $c(\lambda)$ with, in turn, $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ over wavelength λ (for details, e.g., see Wyszecki, G. and Stiles, W. S., 1982; Fairchild, M. D., 2005).

The parallel between the calculation of tristimulus values X, Y, Z and of cone excitations l, m, s is not accidental: the functions $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, $\bar{z}(\lambda)$ are a linear transformation of the cone spectral sensitivities $L(\lambda)$, $M(\lambda)$, $S(\lambda)$, and the tristimulus values X, Y, Z are the same linear transformation of the cone excitations l, m, s.

A two-dimensional chromaticity space with coordinates (x, y) can be derived from tristimulus values X, Y, Z by normalizing; that is, $x = X/(X + Y + Z)$ and $y = Y/(X + Y + Z)$. In this space, the spectral colors form a horseshoe-shaped arc around the point (1/3, 1/3) representing a white with constant radiant power across the spectrum. But the distance between a pair of points, 1 and 2 say, defined by the Euclidean formula $[(x_1 - x_2)^2 + (y_1 - y_2)^2]^{1/2}$ gives a poor guide to the perceived color difference between the corresponding stimuli, which varies according to where the pair of points lies in the space and the orientation of the line joining them. This chromaticity space is perceptually nonuniform; so also is the space of tristimulus values X, Y, Z (Wyszecki, G. and Stiles, W. S., 1982).

2.08.1.3 Related Colors

Although the tristimulus values X, Y, Z of a light (or cone excitations l, m, s) are sufficient to specify the color of a light, and the coordinates (x, y) its chromaticity, they do not describe its appearance: its hue, saturation, lightness, and so on. For example, a monochromatic light of 590 nm, which has chromaticity coordinates $x = 0.575$, $y = 0.424$, appears orange when viewed in isolation in a dark field but brown if surrounded by a brighter, white light.

In natural viewing, colors are normally perceived in relation to each other, as part of a larger scene, and are technically termed related colors (Fairchild, M. D., 2005). Canonical examples of related colors include, in addition to brown, the colors olive green, khaki, and navy blue. Any system for representing color appearance must therefore include some information about the context of the color.

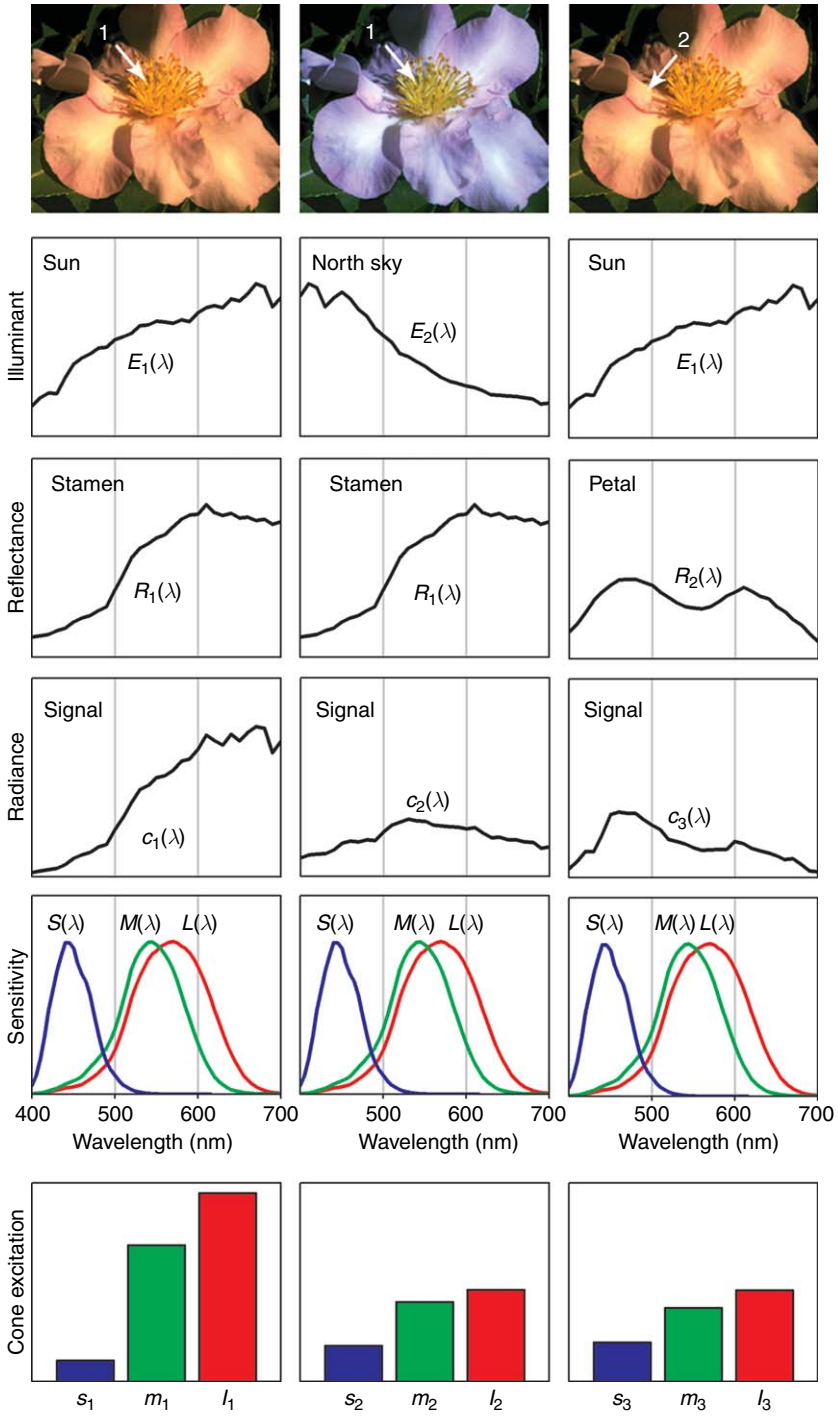

Figure 1 Two areas of a flower under different colored illuminations and the resulting pattern of cone excitations. The spectral reflectance $R_1(\lambda)$ of the stamen (1) under light with spectrum $E_1(\lambda)$ from the sun (correlated color temperature 4000 K) gives a color signal $c_1(\lambda)$ with greatest power at long wavelengths (first column) but a much more even distribution $c_2(\lambda)$ (second column) under a light with spectrum $E_2(\lambda)$ from the north sky (correlated color temperature 25 000 K). As a result, there are marked differences in the triplet of cone excitations (l_1, m_1, s_1) and (l_2, m_2, s_2) (bottom row). By contrast, the spectral reflectance $R_2(\lambda)$ of the petal (2) under sunlight (column 3) gives a different color signal $c_3(\lambda)$ but an almost identical pattern of cone excitations (l_3, m_3, s_3), showing how the effects of illuminant and reflectance spectra may be indistinguishable at a point.

2.08.1.4 CIELAB Color Space

An effect of context is abstracted in CIELAB color space with the specification of a reference white (Wyszecki, G. and Stiles, W. S., 1982; Fairchild, M. D., 2005). This space, defined by the CIE in 1976, has coordinates (L^*, a^*, b^*), which, for a given color, are calculated as follows. First, the tristimulus values X, Y, Z of the color are normalized against the tristimulus values X_n, Y_n, Z_n of the reference white to give X/X_n, Y/Y_n, Z/Z_n. A cube-root transformation is then applied to represent a sensory compression of the response, that is, $(X/X_n)^{1/3}$, $(Y/Y_n)^{1/3}$, $(Z/Z_n)^{1/3}$. Finally, a numerical scaling is applied to $(Y/Y_n)^{1/3}$ to give the coordinate L^* and other numerical scalings applied to the differences $(X/X_n)^{1/3} - (Y/Y_n)^{1/3}$ and $(Y/Y_n)^{1/3} - (Z/Z_n)^{1/3}$ to give the coordinates a^* and b^*, respectively. The coordinate L^* defines a lightness axis, a^* a redness–greenness axis, and b^* a yellowness–blueness axis. Values of L^* range from 0 for black to 100 for a perfectly diffusing white (and possibly >100 for specular reflecting surfaces).

Although not intended as a color-appearance system, some color-appearance attributes can be obtained from L^*, a^*, b^* by defining relative colorfulness or chroma C^*_{ab} as $(a^{*2} + b^{*2})^{1/2}$ and hue h_{ab} as an angle $\tan^{-1}(b^*/a^*)$, in degrees, to form a cylindrical coordinate system (Fairchild, M. D., 2005). Saturation is the colorfulness of area judged in proportion to its brightness.

Figure 2 shows some example CIELAB cylindrical coordinates (L^*, C^*_{ab}, h_{ab}) from a natural scene. The hue angles (third coordinate) of the red and orange petals are 50° and 69°, that is, between the reddish end of the a^* axis and yellowish end of the b^* axis and the hue angle of the purple flower is −57°, that is, between the reddish end of the a^* axis and the bluish end of the b^* axis. The chroma of the points on all three flowers is moderate to high, ranging from 37 to 102, but the chroma of the gray sphere inserted in the scene is low, just 7, although a truly neutral surface would have zero chroma. The flowers and sphere all have similar lightnesses, ranging from 46 to 72.

Figure 2 CIELAB cylindrical color coordinates of points in the image of a natural scene under daylight. The lightness, chroma, and hue angle (in degrees) of each point are indicated.

In CIELAB space, the color difference, denoted by ΔE^*_{ab}, between a pair of stimuli, 1 and 2, say, defined by the Euclidean distance formula $[(L^*_1 - L^*_2)^2 + (a^*_1 - a^*_2)^2 + (b^*_1 - b^*_2)^2]^{1/2}$, is perceptually more uniform than the Euclidean distance formula in the untransformed X, Y, Z space, but large nonuniformities remain. CIELAB space is also designed for viewing scenes under a standardized daylight illuminant, and the device of dividing the tristimulus values of a color by the tristimulus values of a reference white is only partly successful in accommodating changes in the illuminant (Terstiege, H., 1972; Fairchild, M. D., 2005).

Since the introduction of CIELAB space, progressively more accurate and comprehensive color-difference formulas and color-appearance models have been developed for colorimetric applications (Hunt, R. W. G., 1998; Fairchild, M. D., 2005). Thus, the non-Euclidean CIE color-difference formula CIEDE2000 (Luo, M. R. *et al.*, 2001) largely corrects the perceptual nonuniformities of the Euclidean formula in CIELAB space. A subsequent color-appearance model CIECAM02 (Li, C. J. and Luo, M. R., 2005) that takes into account simple surround conditions provides formulas for transforming from CIE tristimulus values to correlates of the perceptual attributes of lightness, brightness, chroma, saturation, colorfulness, and hue, and also an approximately Euclidean distance formula for uniform color differences (Luo, M. R. *et al.*, 2006).

2.08.2 Illuminant and Viewing Media

The influence of context on color appearance may be interpreted as a consequence of our visual experience, of seeing colored surfaces surrounded by other colored surfaces in the natural environment (Judd, D. B., 1940). Here the color appearance of an object may serve as a cue to its identity or condition: the greenness of grass, the redness of ripe fruit. But this is

possible only if color appearance correctly represents in some way surface color – the visual correlate of spectral reflectance – within the limits of metamerism (Section 2.08.1.1).

2.08.2.1 Color Constancy

As noted in Section 2.08.1.1, the color signal $c(\lambda)$ reaching the eye is the wavelength-by-wavelength product of the illuminant spectrum $E(\lambda)$ and the spectral reflectance $R(\lambda)$ at each point in the scene. As a representative of surface reflectance, this color signal is confounded with the properties of the illuminant, for example, whether it has more radiant power at long wavelengths (Figure 1, first column, second row) than at short wavelengths (Figure 1, second column, second row), affecting the resulting triplet of cone excitations l, m, s (bottom row).

Yet in everyday experience, the color appearance of surfaces seems fairly stable. As T. Young (1807) pointed out, a sheet of writing paper appears to retain its whiteness whether illuminated by the yellow light of a candle or by the red light of a fire. This stability is summarized in the notion of color constancy: the constant appearance of object or surface color despite changes in the color of the illumination, and, in modern usage, in scene composition and configuration (Maloney, L. T., 1999). Color constancy is a complex phenomenon (Foster, D. H., 2003; Smithson, H. E., 2005), with a long history of analysis, attracting contributions from G. Monge (1789), T. Young (1807), and H. von Helmholtz (1867), and later by Land, E. H. (1959a; 1959b). But it has proved an elusive phenomenon to quantify, for the stability of color appearance seems to vary with the methods used to measure it, as explained later.

2.08.2.2 Separating Illuminant and Reflectance Spectra

How, in principle, can the confounding effect of the spectrum of the illumination on a scene be eliminated from the color signal at the eye? Suppose that the cone excitations l_0, m_0, s_0 corresponding directly to the illuminant $E(\lambda)$ were available, for example, by reflection from a perfectly diffusing white surface somewhere in the scene. Then an approximately unbiased estimate of a surface color might be obtained by normalizing the excitations l, m, s from the light reflected from this surface against l_0, m_0, s_0, to give l/l_0, m/m_0, s/s_0 (cf. Section 2.08.1.4). In this way, if the illuminant contained an excessive radiant power at long wavelengths, the relatively large value of l would be reduced by the relatively large value of l_0. These scaled cone excitations would be uniquely linked to surface color within the scene, again within the limits of metamerism (Section 2.08.1.1).

This scaling hypothesis was formulated by J. von Kries (1905) to describe the adaptation of the eye to colored lights, albeit not necessarily globally (Ives, H. E., 1912; Smithson, H. E., 2005). Although better known for its role in modeling color constancy, the hypothesis also provided a powerful experimental technique for estimating the spectral sensitivities of the three cone types from color-matching measurements (Wyszecki, G. and Stiles, W. S., 1982).

Formally, von Kries scaling constitutes a diagonal matrix transformation of cone responses (Terstiege, H., 1972; Worthey, J. A. and Brill, M. H., 1986; Brainard, D. H. and Wandell, B. A., 1992), but in practice the extent of the chromatic adaptation provided by this scaling is restricted. Thus, full perceptual compensation for the illuminant occurs only with unsaturated lights. With saturated lights, perceptual compensation is usually incomplete (Judd, D. B., 1940): the red safelight of the photographic darkroom never appears white (Ives, H. E., 1912).

Despite limited experimental evidence, many models of color constancy, including the multiplication rule used in Land's so-called retinex models (Land, E. H., 1959a; 1959b; 1986), assumed implicitly that the formalism of the scaling hypothesis applies also to lights reflected from surfaces. When tested more directly, it was found that the ratios l/l_0, m/m_0, s/s_0 of cone excitations from reflected lights – and not just from those surfaces where one was white – are indeed almost independent of the illuminant (Foster, D. H. and Nascimento, S. M. C., 1994). If cone responses are first transformed so that they are spectrally sharper, for example, by cone-opponent interactions (Foster, D. H. and Snelgar, R. S., 1983; Finlayson, G. D. *et al.*, 1994b), then the independence is even better (Finlayson, G. D. *et al.*, 1994a).

2.08.2.3 Relational Color Constancy

If the eye does not adapt completely to the illumination on part or all of a scene, then color appearance ought to be affected, and, in turn, judgments of surface color. But not all judgments that appear to involve color constancy involve complete chromatic adaptation. For example, in the natural world, surfaces are often seen partly in direct light and partly in shadow, but the shadowed region appears to have the

Figure 3 Images of a natural scene containing a test sphere (bottom left in each image) under different illuminations. In the upper left and right images, the illuminant is north sky light (correlated color temperature 25 000 K) and sunlight (4000 K), respectively, and the sphere is covered with gray paint. In the lower left image, the illuminant is sunlight and the sphere is covered with blue–gray paint. In the lower right image, the illuminant is a mixture of sunlight and north sky light (6500 K), and the sphere is covered with gray paint.

same surface color as the unshadowed region, even though it is simultaneously seen to be less bright and generally more blue (Arend, L. E. *et al.*, 1991). This apparently paradoxical separation of percepts was identified by Georg Christoph Lichtenberg in 1793 in a letter to Johann Wolfgang von Goethe thus: "In ordinary life we call white, not what looks white, but what would look white if it was set out in pure sunlight" (Joost, U. *et al.*, 2002, p. 302).

To make effective surface-color judgments in these conditions, an observer could use the perceived color relations between parts of a scene. For example, in Figure 3, in the upper left and upper right images of a scene, the color of the light reflected from the sphere in the bottom left corner is clearly different; nevertheless, it is possible to decide that the sphere has the same surface color by comparing it with, for example, the nearby leaves. By contrast, in the lower left image, although the color of the light reflected from the sphere is the same as in the upper left image, it is possible to decide that the sphere has a different, bluish, surface color, again by comparing it with nearby leaves. In the upper left and upper right images, the perceived relations between the colors are preserved; in the upper left and lower left images, they are not (the lower right image is discussed in Section 2.08.4.4).

Relational color constancy refers to the constancy of perceived color relations under illuminant changes, or other viewing conditions (Foster, D. H. and Nascimento, S. M. C., 1994), and has an operational interpretation described later (Section 2.08.4.5). It is distinct from the phenomenon of related colors, which requires other colors for their perception.

Notice that the comparisons just described may be made simultaneously with fixed gaze, or sequentially by moving the eye from one image to the other (Cornelissen, F. W. and Brenner, E., 1995), or with fixed gaze and the illumination on the scene changing, or any combination of these. Although some chromatic adaptation does take place with these images, either locally or globally, or both, it is insufficient to eliminate the perceived differences in illumination.

2.08.3 Sensory and Perceptual Cues

If color constancy is achieved partly or wholly by scaling cone responses – or their transforms – to compensate for the color of the illumination on a scene, then information about the illuminant is required. But the illuminant itself may not be visible; for example, the light may come from behind the observer, and there may be no designated perfectly diffusing white surface in the scene from which the corresponding cone excitations l_0, m_0, s_0 representing the illuminant can be derived. Other strategies are needed to obtain the required information.

2.08.3.1 Estimating the Illuminant

In natural scenes, there are several indirect cues to illuminant color (Maloney, L. T., 2002). One is the spatial average of the colors in the scene, estimated visually by global mechanisms or by local mechanisms combined with eye movements (D'Zmura, M. and Lennie, P., 1986), or both. If the color gamut of the surfaces is sufficiently large, then their average should be chromatically neutral (the gray-world hypothesis: Evans, R. M., 1946/1951; Buchsbaum, G., 1980; Land, E. H., 1986), and any bias away from neutral should represent the illuminant color. Another indirect cue is the color of the highest-luminance surface in the scene. As it reflects the most light, it is most likely to be white or specular, and therefore any bias should represent the illuminant color (the bright-is-white hypothesis: Land, E. H. and McCann, J. J., 1971; Gilchrist, A. *et al.*, 1999). These two cues normally covary, but when pitted against each other, the spatial-average cue seems to dominate the highest-luminance cue, except when the scene has few surfaces (Linnell, K. J. and Foster, D. H., 2002).

Mutual illumination (Bloj, M. G. *et al.*, 1999) and specularities with nonuniform surfaces (Yang, J. N. and Maloney, L. T., 2001) may also be used to infer the scene illuminant, and, over a limited region, luminance-color correlations (Golz, J. and MacLeod, D. I. A., 2002; Granzier, J. J. M. *et al.*, 2005) may be used in a similar way.

2.08.3.2 Color Contrast and Variance

The cues to the scene illuminant provided by the spatial average and the brightest surface or specularity represent two spatial extremes in sampling the visual environment. The influence of more intermediate-range sampling is found in the classical color-contrast or chromatic-induction effects whereby the hue of a stimulus is shifted away from that of a surround field. These effects may be interpreted as local illuminant compensation (Hurlbert, A. and Wolf, K., 2004), being limited to about 1° of visual angle from the point of gaze (Brenner, E. *et al.*, 2003, see also Barbur, J. L. *et al.*, 2004), although some modulatory effects on color appearance may extend to 10° of visual angle (Wachtler, T. *et al.*, 2001).

Other spatial factors influencing color appearance in variegated scenes include differences in texture, which weaken chromatic-contrast induction (Hurlbert, A. and Wolf, K., 2004), and chromatic variation in a background field: areas appear more vivid and richly colored against low-contrast, gray surrounds than against high-contrast, multicolored surrounds (Brown, R. O. and MacLeod, D. I. A., 1997; Shevell, S. K. and Wei, J., 1998; Brenner, E. and Cornelissen, F. W., 2002; Brenner, E. *et al.*, 2003).

2.08.3.3 Spatial Ratios of Cone Excitations

Unlike color constancy, relational color constancy (Section 2.08.2.3) does not require an estimate of the illuminant on the scene. In fact, the spatial ratios of cone excitations generated in response to light reflected from pairs of surfaces or groups of surfaces may provide sufficient cue to the stability or otherwise of surface color. As already noted (Section 2.08.2.2), such ratios have the property of being almost exactly invariant under changes in illuminant, both with artificial scenes of colored papers (Foster, D. H. and Nascimento, S. M. C., 1994) and with natural scenes (Nascimento, S. M. C. *et al.*, 2002), as illustrated in Figure 4 for long-, medium-, and short-wavelength cones in turn.

In theory, temporal ratios of cone excitations may also be calculated with similar effect. Eye movements back and forth across an edge separating different surfaces could define a ratio signal over recent time that, like spatial ratios, is almost exactly invariant under changes in illuminant. In making surface-color matches across two simultaneously presented Mondrian-like images, experimental observers switch gaze between test and reference surfaces with increasing frequency just before a match is made (Cornelissen, F. W. and Brenner, E., 1995). Spatial (and temporal) ratios may also be calculated across postreceptoral combinations (Zaidi, Q. *et al.*, 1997); across spatial averages of cone excitations (Amano, K. and Foster, D. H., 2004); and across the two eyes, suggesting the involvement of binocularly driven processes (Nascimento, S. M. C. and Foster, D. H., 2001; Barbur, J. L. *et al.*, 2004; see also Section 2.08.7.2).

The invariance or otherwise of these ratios may explain performance in several color-vision tasks (Westland, S. and Ripamonti, C., 2000; Ripamonti, C. and Westland, S., 2003; Foster, D. H. *et al.*, 2001b), including asymmetric color matching (Tiplitz Blackwell, K. and Buchsbaum, G., 1988). The calculation of ratios is a general device, which need not be restricted to primate or indeed vertebrate vision (Section 2.08.7). Bumblebees appear to make similar calculations to encode contrast relations between distinct elements of complex scenes (Lotto, R. B. and Wicklein, M., 2005).

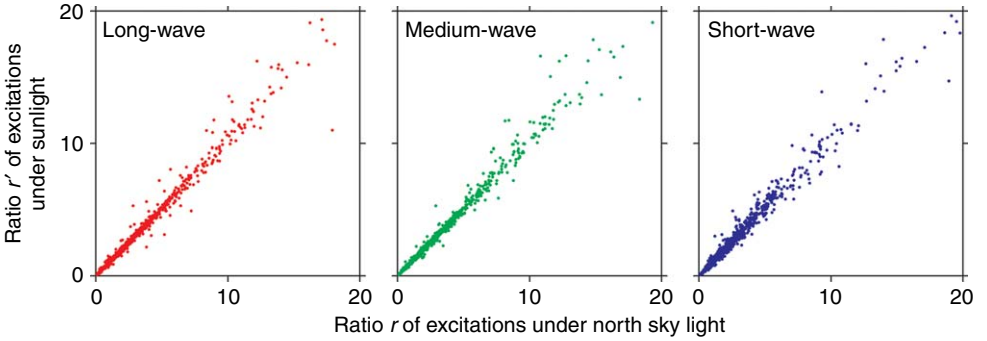

Figure 4 Scatterplot of ratios of cone excitations for long-, medium-, and short-wavelength-sensitive cones. Each point represents a pair of ratios r and r' of excitations in a cone class produced by light from a pair of surfaces drawn at random from a set of 25 natural scenes under, respectively, north sky light and sunlight, with correlated color temperatures 25 000 K and 4000 K. The mean deviation of pairs of ratios from equality is about 5% (see Foster, D. H. and Nascimento, S. M. C., 1994; Nascimento, S. M. C. *et al*., 2002). Number of points in each graph is approximately 2400.

As illustrated earlier (Section 2.08.2.3, Figure 3), the cue provided by spatial cone-excitation ratios, unlike the scaling of cone responses defined by von Kries adaptation, has the advantage that it allows the separation of judgments about the stability of surface colors from judgments about the color of the illumination, which, environmentally, may be equally important (Jameson, D. and Hurvich, L. M., 1989).

2.08.4 Measuring Perceived Surface Color

Given that with one cue or another it is possible to estimate surface color from the light reflected from a scene, how is the ability to make this estimate assessed experimentally in the laboratory? There are four main methods of measurement, each of which is limited in different ways (Foster, D. H., 2003).

2.08.4.1 Color Naming and Scaling

The most direct approach to measuring color constancy is to test the consistency of color naming under different lights. Although certain color terms are basic (Berlin, B. and Kay, P., 1969; Uchikawa, K. and Boynton, R. M., 1987), observers may be given a free choice; for example, if they call an intense yellow surface cadmium yellow under one illuminant, do they use the same name under a different illuminant? In practice, however, even when the illuminant is constant, observers use the same name for other shades of intense yellow. The problem is that there are many more distinguishable surface colors, perhaps more than two million (Pointer, M. R. and Attridge, G. G., 1998), than can be named accurately or consistently.

It is possible to increase the precision of color naming by adjoining a numerical scale, although the system is then no longer purely categorical (Foster, D. H., 2003). For example, observers may be asked to judge how red, green, blue, and yellow a test patch appears on a fixed scale of numbers (Schultz, S. *et al*., 2006).

2.08.4.2 Setting Unique Hues

In contrast with color names in general, the so-called unique hues red, green, blue, and yellow can be set by an experimental observer precisely (Valberg, A., 1971). Surface-color judgments under different illuminants may then be measured by finding a color setting that excludes the other hues: a yellow test stimulus, for example, is set so that it is neither reddish nor greenish (Arend, L. E., 1993; Shevell, S. K. and Wei, J., 1998). But the method is necessarily limited to these four hues.

2.08.4.3 Achromatic Adjustment

Setting a color to neutral is the logical intersection of setting unique hues: a white or gray test surface is adjusted so that it appears neither reddish nor greenish nor bluish nor yellowish. Although used to measure color constancy, achromatic adjustment strictly records only the observer's estimate of local illuminant color. But by measuring the bias of this estimate, it may be used to probe the effects of scene

structure such as local chromatic context (Brainard, D. H., 1998; Kraft, J. M. and Brainard, D. H., 1999) and to reveal the role of memory in surface-color judgments (Smithson, H. and Zaidi, Q., 2004; Hansen, T. *et al.*, 2006).

2.08.4.4 Asymmetric Color Matching

Color naming and setting unique hues both involve color identification, but asymmetric color matching does not. Rather, it simply requires a match to be made between a test and a reference surface under different lights (Wyszecki, G. and Stiles, W. S., 1982). For example, with the lower left and right images of Figure 3, an experimental observer would adjust the color of the (initially gray) test sphere in the right scene under the mixture of sunlight and north sky light so that it appears to have the same color as the (blue) sphere in the left scene under sunlight. The scenes may be viewed simultaneously or sequentially. This surface-color match is also referred to as a paper match (Arend, L. and Reeves, A., 1986), owing to its association with test samples taken from the Munsell Book of Color (Munsell Color Corporation, 1976).

Color matching ensures only the equivalence of two stimuli, not necessarily that they produce the same color percepts (Foster, D. H., 2003). In principle, observers need judge merely whether the relation between the color of one surface in the scene and the color of one or more others is the same as when the scene is viewed under a different illuminant; in other words, whether relational color constancy holds (Section 2.08.2.3). Estimating the illuminant seems to be unnecessary, as reliable surface-color matches are possible with minimalist scenes of just two surfaces, which provide little information about the illuminant (Tiplitz Blackwell, K. and Buchsbaum, G., 1988; Arend, L. E. *et al.*, 1991; Amano, K. and Foster, D. H., 2005).

2.08.4.5 Discriminating Illuminant from Reflectance Changes

A completely operational approach to measuring surface-color perception is to ask observers to distinguish between illuminant and surface-reflectance changes in a scene (Craven, B. J. and Foster, D. H., 1992; Nascimento, S. M. C. and Foster, D. H., 1997; Zaidi, Q., 2001). Performance in one such task has been found to be fast, accurate, and effortless, suggesting the spatially parallel detection of deviations from constancy in spatial cone-excitation ratios over the visual field (Foster, D. H. *et al.*, 2001b).

2.08.5 Levels of Color Constancy

The methods of measuring surface-color perception outlined in Section 2.08.4 vary in the kinds of information they provide. For accurate results, it is important to have a criterion that refers implicitly or explicitly to surface color; otherwise, other aspects of color appearance may determine performance.

2.08.5.1 Dual Representations

When experimental observers are asked to match a test surface for hue and saturation (e.g., the sphere in the upper left and right images of Figure 3), the level of color constancy obtained is much poorer than when they are asked to make a paper match. One explanation (Arend, L. and Reeves, A., 1986) of these different levels has been based on the roles played by two kinds of constancy process, which have already been mentioned (Section 2.08.2).

In one process, the eye becomes accustomed to the new illuminant with both light adaptation (von Kries, J., 1905; Whittle, P., 1996) and contrast adaptation (Webster, M. A. and Mollon, J. D., 1995; Brown, R. O. and MacLeod, D. I. A., 1997). Mechanisms with multiple time courses may be involved (Fairchild, M. D. and Reniff, L., 1995; Rinner, O. and Gegenfurtner, K. R., 2000). As hue and saturation are preserved under the change in illuminant, a paper that looks unique yellow under direct sunlight would continue to look unique yellow under, say, the greenish light reflected or transmitted beneath a tree. In the other process there is little opportunity for this adaptation, as when the eye moves over a scene patterned by light and shade (Zaidi, Q. *et al.*, 1997). Hue and saturation change when the illuminant changes, but they are interpreted as resulting from constant surface colors – constant spectral reflectances – under varying illumination. The paper that looks unique yellow under direct sunlight would in fact look greenish-yellow under a tree but be clearly identifiable as yellow paper. The differences in the completeness of these two processes affect the level of color constancy achieved in the two kinds of task (Bäuml, K.-H., 1999; Logvinenko, A. D. and Maloney, L. T., 2006).

2.08.5.2 Role of Task and Stimulus

On a continuous scale in which perfect color constancy is 1 and perfect inconstancy 0 (Arend, L. E. *et al.*, 1991), average levels of constancy have, depending on task

and stimulus, been reported as 0.79–0.87 for asymmetric color matching in computer-simulated images of flat Mondrian-like patterns of different colored Munsell papers (Bäuml, K.-H., 1999; Foster, D. H. *et al.*, 2001a); 0. 61 for asymmetric matching of real Munsell papers (Brainard, D. H. *et al.*, 1997) and 0.82 for achromatic adjustment of a test surface in an array of real Munsell papers (Brainard, D. H., 1998); 0.83 for achromatic adjustment of a test surface in a three-dimensional geometric tableau (Kraft, J. M. and Brainard, D. H., 1999); 0.70 for hue scaling of a test patch in a computer-simulated three-dimensional geometric tableau (Schultz, S. *et al.*, 2006); and 0.86 for asymmetric matching of a test object in a real three-dimensional geometric tableau (de Almeida, V. M. N. *et al.*, 2004) and 0.80 for discriminating illuminant from reflectance changes with similar stimuli (Nascimento, S. M. C. *et al.*, 2005a).

These constancy indices represent sometimes large variations across individual observers and stimuli, but systematic stimulus effects are identifiable. For example, with images of rural and urban scenes, 70% of the total variance in constancy indices can be explained by a combination of spatially averaged differences in spatial cone-excitation ratios, chroma, and hue (Foster, D. H. *et al.*, 2006a). Interestingly, three-dimensional scenes and natural scenes seem to provide no special advantage over flat and artificial scenes in eliciting high levels of constancy.

2.08.6 Color Appearance in Natural Environments

The abstract geometric displays used in laboratory measurements of color appearance usually have large, uniformly distributed color gamuts. By contrast, surfaces in natural scenes have smaller, more biased gamuts.

2.08.6.1 Colors of Natural Surfaces

The distribution of chromaticities of surfaces in natural scenes is dominated by browns, greens, and blues, from earth, vegetation, and sky (Hendley, C. M. and Hecht, S., 1949; Burton, G. J. and Moorhead, I. R., 1987; Osorio, D. and Bossomaier, T. R. J., 1992; Webster, M. A. and Mollon, J. D., 1997). More detailed analysis of these spectra suggests that the spectral positions of the long- and medium-wavelength-sensitive pigments (Figure 1) are optimal for primates discriminating ripe fruit or young leaves against a background of mature foliage (Sumner, P. and Mollon, J. D., 2000; Dominy, N. J. and Lucas, P. W., 2001; Lucas, P. W. *et al.*, 2003), but color vision is also important more generally for identifying objects and surfaces in variegated environments (Chiao, C.-C. *et al.*, 2000; Osorio, D. and Vorobyev, M., 2005). The fact that metamerism (Section 2.08.1.1) is rare in natural scenes (Foster, D. H. *et al.*, 2006b) suggests the sufficiency of trichromatic vision, that is, more cone classes are unnecessary.

2.08.6.2 Discriminating and Identifying Natural Surfaces

How well does color appearance allow us to identify objects in natural scenes under different illuminants? Performance depends not only on color constancy but also on other factors, such as the number of different colored surfaces present that might act as distractors. For example, if just two surfaces are sampled, there is little risk of confusion with a change in lighting: their color appearance will generally be different, and this difference will persist when the illuminant changes. But as the number of surfaces increases, the risk of confusion increases.

The success of color-appearance models (Sections 2.08.1.4 and 2.08.2.2) in predicting object identification in natural scenes under different illuminants can be quantified in a quite general way by applying methods from information theory (Cover, T. M. and Thomas, J. A., 1991). For any particular model, the magnitude of the information preserved from a scene varies surprisingly little from scene to scene, suggesting that the sensory coding of surface color in natural scenes can be optimized independent of viewing direction for any particular range of illuminants (Foster, D. H. *et al.*, 2004).

2.08.7 Physiological Mechanisms

Color appearance is the product of multiple stages of processing in the visual system (Walsh, V., 1999; Hurlbert, A. and Wolf, K., 2004), but its precise neural basis remains unresolved, partly because of different experimental criteria used to assess it, as indicated earlier.

2.08.7.1 Processing in Retina and Lateral Geniculate Nucleus

Significant chromatic adaptation takes place retinally. Microelectrode recordings from monkey horizontal

cells have shown that, consistent with the von Kries scaling hypothesis, adaptation is cone-specific at moderate light levels, although it is also incomplete and necessarily spatially local (Lee, B. B. *et al.*, 1999). Recordings from goldfish, which can make color-constant judgments (Neumeyer, C. *et al.*, 2002), have indicated that cone synaptic gains are modulated by the horizontal cell network in such a way that the ratios of cone outputs are almost invariant with the illuminant spectrum (Kraaij, D. A. *et al.*, 1998; Kamermans, M. *et al.*, 1998). Normalizing shifts in chromatic sensitivity have also been found in monkey parvocellular lateral geniculate neurons and their retinal afferents (Creutzfeldt, O. D. *et al.*, 1991).

A retinal contribution has also been revealed in humans by functional magnetic resonance imaging (Wade, A. R. and Wandell, B. A., 2002) and in subjective reports of color-induction in hemianopia (Pöppel, E., 1986).

2.08.7.2 Cortical Processing

A potential basis for the cortical calculation of spatial cone-excitation ratios is provided by double-opponent cells, which have been found in area V1 of the monkey visual cortex and which are sensitive to spatial chromatic contrast (Conway, B. R., 2001; Conway, B. R. and Livingstone, M. S., 2006). These cells are probably different from those cells in V1 that respond strongly to homogenous colored patches on large backgrounds (Wachtler, T. *et al.*, 2003) and which may contribute to chromatic-induction effects found in humans (Wachtler, T. *et al.*, 2001), including, the effect of colored patches remote from the test stimulus (Section 2.08.3.2).

Asymmetric color matching and color naming by patients with lesions higher than V1 also suggest that chromatic-contrast effects are calculated in area V1 or lower (Hurlbert, A. and Wolf, K., 2004). One patient with cerebral achromatopsia, despite being unable to match or name surface colors, was found able to discriminate changes in spatial cone-excitation ratios with simple scenes, but not with complex ones, suggesting a failure of integrative processes over the visual field (Hurlbert, A. C. *et al.*, 1998; see also Kentridge, R. W. *et al.*, 2004; Barbur, J. L. *et al.*, 2004).

Reminiscent of Land's experiments with Mondrian-like displays (Land, E. H., 1959a), cells in area V4 of the monkey visual cortex have been found to respond to a red patch when an entire multicolored Mondrian pattern was illuminated by long-, medium- and short-wavelength lights, but not with long-wavelength light alone (Zeki, S., 1980). Conversely, with lesions to V4, monkeys experience difficulty in identifying a colored surface under different illuminants (Walsh, V. *et al.*, 1993), and patients with lesions to the lingual and fusiform gyri, which include part of putative human area V4, have deficits in surface-color perception (Kennard, C. *et al.*, 1995; Clarke, S. *et al.*, 1998). Color constancy can also be selectively impaired after circumscribed unilateral lesions in parieto-temporal cortex (Rüttiger, L. *et al.*, 1999).

2.08.7.3 Inherited Color-Vision Deficiency

The abnormalities of inherited color-vision deficiency are evident on traditional clinical color-vision testing. Yet red-green dichromats, protanopes and deuteranopes, who have, respectively, no long- and medium-wavelength-sensitive pigments (Deeb, S. S., 2004), are able to identify surface colors under a fixed illuminant (Cole, B. L. *et al.*, 2006). They can also make achromatic settings (Rüttiger, L. *et al.*, 2001) and discriminate reflectance changes from illuminant changes with Mondrian-like patterns under different illuminants (Baraas, R. C. *et al.*, 2004), although their performance, and that of tritanopes (Foster, D. H. *et al.*, 2003), who have no short-wavelength-sensitive pigment, may be more variable and poorer than that of normal controls.

Deuteranomalous trichromats, whose medium-wavelength-sensitive pigment is replaced by a pigment closer to the long-wavelength-sensitive pigment (Deeb, S. S., 2004), can discriminate random reflectance changes from illuminant changes in natural scenes about as well as normal trichromats can (Baraas, R. C. *et al.*, 2006). Protanomalous trichromats, whose long-wavelength-sensitive pigment is replaced by a pigment closer to the medium-wavelength-sensitive pigment, perform somewhat less well.

The reasons for these variations in performance are incompletely understood. Possible explanatory factors include the influence of rod signals at lower light levels; the availability of cues from spatial ratios of cone excitations or of opponent combinations of cone excitations with altered spectral coverage; differences between stimuli based on natural and artificial reflectance spectra; and, for dichromats, the direction in chromaticity space of the loci of indistinguishable colors relative to the direction of the illuminant change. In general, however, individuals with color-vision deficiency may be less disadvantaged in judging natural surface colors than might be expected from clinical color-vision data.

> Like beauty and color, motion is in the eye of the beholder.

2.09.1 Introduction

The physical phenomenon, motion, can easily be defined as an object's change in position over time. An animal that can detect moving predators, prey, and mates has a clear survival advantage and this evolutionary pressure has presumably led to the development of neural mechanisms sensitive to motion. However, the combined effect of evolutionary circumstance, conflicting demands on the perceptual apparatus, and limitations of biological hardware have led to motion detection mechanisms that are far from perfect. A neural motion detection mechanism may not respond appropriately to all kinds of changes in position, and it may respond to some inputs that are not changes in position at all. It is in this sense that I subscribe to the quote from Watson A. B. and Ahumada A. J. (1985) at the start of this chapter; (the percept of) motion is constructed by the beholder's imperfect mechanisms for the detection of (physical) motion. The goal of this chapter is first to elucidate the principles that the brain relies on to detect motion. But second, to point out that strict adherence to those principles is quite rare, and that imperfect implementations are the rule, rather than the exception.

Research into motion detection mechanisms is strongly model-driven. Many studies are guided by particular views of the computations that are needed to detect motion; they aim to uncover the algorithms used by the brain, and describe the details of the neural implementations (Marr, D., 1982). Before delving into the details of motion detection mechanisms, a brief view of motion detection along these lines will be given.

2.09.1.1 Computations

Three views of the computations required for motion detection have emerged. The first states that a motion detector must compute whether the presence of light at one position is followed by light at another position. To detect motion, light has to be detected at both positions and times, and then compared. In the second view of motion, it is a continuous process of change. This view states that a moving object traces out an oriented light distribution in space–time. To detect motion, this orientation needs to be measured. The third view starts from the observation that motion can only be observed when there is both a temporal and a spatial change in light intensity. To detect motion, both need to be measured and compared. Each of these views suggests a different emphasis on algorithms that are relevant to compute motion (Figure 1).

2.09.1.2 Algorithms

The computations required by the first view can be performed by detecting light in the first position, delaying the signal, and multiplying it with the signal arising from the (undelayed) signal arising from the detector in the second position. This algorithm essentially performs a space–time autocorrelation. The computations of the second view require an estimate of space–time slant. This can be done by convolving the image with filters that are oriented in space–time. The computations of the third view require the estimation of both the spatial and temporal gradients in light intensity of an image. In abstract terms, such gradients can be determined by convolving the image with appropriate (differentiating) filters. The motion signal is then given by the ratio of the temporal and spatial gradients. Each of these algorithms requires different neural hardware for its implementation.

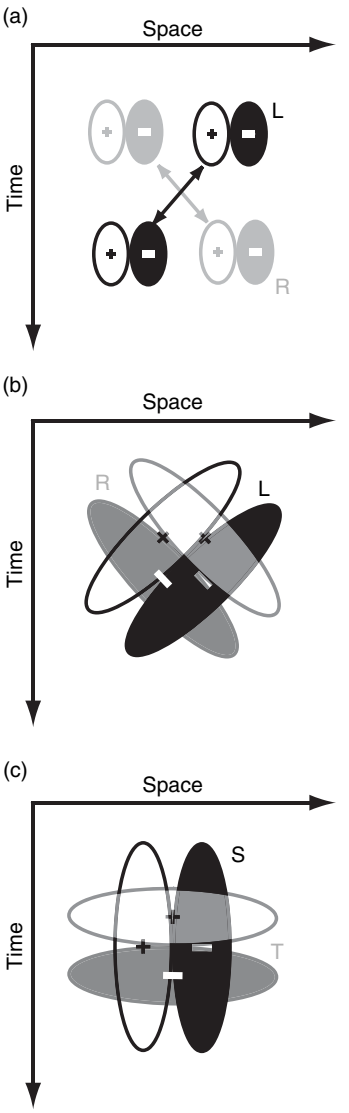

Figure 1 Three views of motion detection. (a) The Reichardt detector makes use of sensors that are displaced in space and time with respect to each other. By multiplying their outputs (indicated by the arrows), one can create a rightward (R) or leftward (L)-selective detector. (b) The motion energy detector uses overlapping sensors that are sensitive to rightward (R) or leftward (L) space–time slant. (c) The gradient detector uses overlapping detectors, sensitive to either spatial (S) or temporal (T) change. Adapted from Johnston, A. and Clifford, C. W. 1995b. A unified account of three apparent motion illusions. Vision Res. 35, 1109–1123.

2.09.1.3 Implementations

In the space–time correlation view, temporal delays and multiplication are the essential ingredients to detect motion. While temporal delays are part and

parcel of neural responses, typical synapses only add or subtract input signals, and multiplication of two signals is not as straightforward. Much of the research at the implementation level is therefore devoted to understanding if and how neurons can perform a multiplication. In the space–time orientation view, neurons' space–time receptive fields (RFs) must be slanted. Research in this tradition therefore concentrates on measuring detailed properties of space–time RFs. In the space–time gradient view, neurons' space–time response maps should match those of differentiating filters. Research in this tradition looks for such properties in visual neurons.

The three views of motion detection (correlation, orientation, and gradients) will be used as the skeleton to organize this chapter. It should be noted, however, that they are not mutually exclusive or even entirely independent. In fact, under some assumptions about the visual input, the detectors based on the three views become formally identical at their output levels (Adelson, E. H. and Bergen, J. R., 1985; van Santen, J. P. and Sperling, G., 1985; Bruce, V. *et al.*, 2003). On the other hand, these formal proofs should not be misconstrued to imply that the three computations, algorithms, and implementations are all the same. Behavioral methods may not be able to distinguish among some of the models because they only have access to the output of the motion detection mechanisms. But, as will be seen, neurophysiological methods can gain access to intermediate steps in the computations that are distinct.

The goal is to present some of the salient evidence that either provides support for one of the models or allows us to distinguish among the correlation, orientation, or gradient models. At the same time, however, it is important to realize that the brain may not perform any of these computations perfectly. Such imperfections may have arisen from competing constraints during the evolution of the visual system, or the limitations of biological hardware. As such, imperfections may be a nuisance in a model of motion detection, but in fact, they can be instructive in the larger view of the organization of the brain.

Sections 2.09.3, 2.09.4, and 2.09.5 review the literature on correlation, orientation, and gradient models, respectively. Before delving into the literature, however, some of the methods and terminology that have proven useful in the study of motion detection are discussed.

2.09.2 Research on Motion

Motion mechanisms can be studied by comparing the (behavioral or neural) response to a stimulus moving in one direction with that same stimulus moving in another direction. For direction-selective neurons, this is often reduced to responses to a stimulus moving in the preferred and the opposite, antipreferred direction. Many studies use sinusoidal gratings as the stimulus. The reason for using gratings is that, as long as a neuron (or mechanism) is well described as a linear system, the response to sinusoidal gratings can be used to predict the response to an arbitrary stimulus (Movshon, J. A. *et al.*, 1978a; 1978b). This Fourier analysis is only truly applicable to linear systems, which neurons in general and direction-selective neurons in particular are not. Nevertheless, the Fourier method has proven to be useful and much of the terminology in the field is derived from it.

To study the internal mechanisms of a motion detector, a sinusoidal grating may not always be the best choice. Although somewhat counterintuitive at first, even moving stimuli may not be the optimal stimuli to study motion mechanisms. The reason for this is that any motion mechanism worth considering would predict that motion in the preferred direction evokes a larger response than motion in the antipreferred direction. Hence, finding such responses does not tell us much about the internal mechanisms of the detector.

Many studies use flashed stimuli to characterize the response of motion detection mechanisms. A single flash by definition does not contain a motion signal, but nevertheless, it often activates motion detectors (and therefore may even appear to move). The minimal true motion signal is generated by two successive flashes. Thus, by comparing the response of a motion detector to two successive flashes with the response evoked by those same flashes presented in isolation, the motion-specific response properties can be extracted.

A further elaboration of this technique leads to the white noise analysis of nonlinear systems identification (Marmarelis, P. Z. and Marmarelis, V. Z., 1978). In this approach, the stimulus is a noisy pattern whose intensity varies rapidly and randomly. This can be viewed as a stimulus with multiple flashes occurring at the same time. Given enough time, all possible patterns will be presented to the detector, the responses to all possible patterns will be recorded, and the complete input–output relationship can be determined. In the finite

time available for an experiment this situation can of course only be approximated. Typically these approximations take into account the first-order response (response to a flash at a particular position) and the second-order response (interaction between two flashes separated in space and time).

With these methods it is possible to measure the properties that have proven to be useful to describe motion detection mechanism and that will recur throughout this chapter:

Direction selectivity (DS). The property that a mechanism (e.g., a neuron) responds differently when a stimulus moves in one direction than when that stimulus moves in the opposite direction.

Space–time response map or space–time RF. The response at time t to a flash presented at time zero at some position x. Because only one-dimensional motion will be considered, the space–time response map is two-dimensional.

Space–time interaction map. The response enhancement observed for a stimulus presented at ($t1$, $x1$), when another stimulus has already been presented at ($t2$, $x2$). This is a four-dimensional map. Often, however, the relative rather than the absolute time and position of the flashes matter. In such cases, the interaction map becomes two-dimensional and represents the enhancement in the response to a flash caused by the presentation of another flash dt earlier and at a distance of dx.

In the sections that follow, these measures of the internal properties of a motion detector will be used extensively to characterize experimental data, and to distinguish between models.

2.09.3 Space–Time Correlation

The study of the neural mechanisms of motion detection started in earnest with work on insects by Hassenstein, Reichardt, and Varju, in the early 1950s. Considering the faceted eyes of insects, it is natural to view motion as the detection of successive activation of neighboring ommatidia.

2.09.3.1 The Reichardt Detector

Hassenstein B. and Reichardt W. (1956) proposed the first formal model of motion detection on the basis of careful observations of the behavior of the beetle (*Chlorophanus viridis*). When placed in a moving environment, this beetle has the instinctive reaction to turn with the motion of the environment. Presumably it does this to keep moving in a direction that is constant with respect to the environment. Later studies have made use of similar optomotor responses in houseflies, blow flies, and locusts to gain access to their percept of motion.

By putting the beetle on a Y-globe (or *Spangenglobus*, in German), and surrounding it by a cylinder marked with vertical patterns, Hassenstein B. and Reichardt W. (1956) were able to quantify the beetle's motion percept (Figure 2). For instance, when they first presented a bright (+1) bar such that its light hit a specific ommatidium and then another bright bar to stimulate the nearest ommatidium to the left, the beetle turned toward the left. When a dark (−1) bar was followed by a dark bar on the left, the beetle also turned to the left. But, when a bright (+1) bar followed a dark (−1) bar on the left, the beetle turned to the right. From these key observations, they concluded that a simple algebraic multiplication of the contrasts of the visual patterns could underlie the motion response.

Figure 2 A beetle on a Spangenglobus. The beetle is glued to the black pole which holds it stationary in space. When it is lowered onto the y-maze globe, it instinctively grabs it and starts walking along the ridges. When it comes to a y-junction, it must make a decision to go right or left. This decision can be influenced by presenting motion in the environment (© Freiburger Universitaetsblaetter)

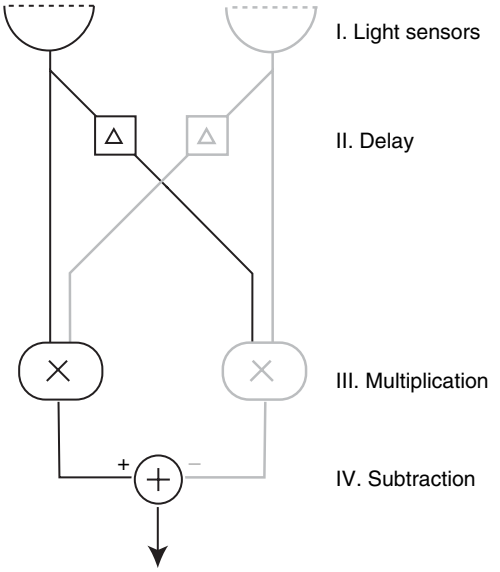

Figure 3 The (Hassenstein-) Reichardt detector. The light sensors represent the beetle's ommatidia. Signals from two neighboring ommatidia (I) are multiplied at stage III. One of the two input signals, however, is first delayed (II). The output of the multiplication stage in black is selective for rightward motion. This selectivity is enhanced in the last stage (IV) by subtracting the output of a leftward-selective subunit (in gray) from that of the rightward-selective subunit.

Additionally, they found that, for any given two-bar sequence, the optomotor response was strongest when there was about 250 ms between the two stimuli. A simple model that captures these properties is shown in Figure 3.

The first stage represents the input from two neighboring ommatidia. At the second stage, the input from one location is delayed. The third stage implements the multiplication that Hassenstein B. and Reichardt W. (1956) observed to underlie the beetle's behavior. This is an essential nonlinear operation, without which no DS could be generated in the time-averaged signal (Poggio, T. and Reichardt, W., 1973; 1981). To create a signal whose average value indicates the direction of motion, this stage can also average the signal over time. Finally, the output of a leftward-selective motion detector is subtracted from that of a rightward detector in the fourth stage. This subtraction greatly improves the selectivity of the detector (Borst, A. and Egelhaaf, M., 1990). The result is a single-valued output that is positive for rightward motion and negative for leftward motion. It could be imagined that such a number is fed straight into a motor control system to generate the beetle's following response. Formally, it can be shown that the output of this stage is the autocorrelation of the input signal (Reichardt, W., 1961). In other words, the detector determines how much a signal in one location is like the signal at a later time at a position to the right. If this autocorrelation is positive, motion is to the right; if it is negative motion is to the left.

2.09.3.2 Behavioral Evidence

The Reichardt detector makes some very specific and sometimes counterintuitive predictions about motion perception that have been tested in detail. A few of these will be highlighted here.

2.09.3.2.1 Facilitation

When a stimulus jumps from one position to the next and increases its contrast at the same time, the Reichardt model predicts that the motion signal is proportional to the product of the prejump and postjump contrast. As long as stimulus contrast is small enough, this is indeed the case in many insects (Reichardt, W., 1961; McCann, G. D. and MacGinitie, G. F., 1965; Buchner, E., 1984). For higher contrasts, however, further increases in contrast no longer strengthen the motion signal. Hence, a complete model should incorporate some kind of saturation or normalization of the response for high contrast.

van Santen J. P. and Sperling G. (1984) investigated this issue in humans and showed that, at least at low contrast, the motion signal indeed increased as the product of prejump and postjump contrasts. This clearly argues in favor of facilitation and even suggests that this facilitation takes the form of a multiplication. More recent experiments, however, show that perception is affected differently depending on whether the prejump or postjump stimulus contrast is increased (Morgan, M. J. and Chubb, C., 1999). Neither of these effects would be expected in a pure Reichardt detector, but may be explained by adding noise sources and contrast normalization mechanisms to the motion detector (Solomon, J. A. *et al.*, 2005).

2.09.3.2.2 Reverse-Phi

The multiplication in the Reichardt model ensures that motion detection does not depend on the polarity of the contrast of a moving object (dark objects lead to the same motion signals as bright objects). At

the same time, however, the multiplication causes a reversal of motion direction for stimuli whose contrast changes polarity. This inversion of motion direction with an inversion of contrast polarity during a motion step is called reverse-phi and has been observed behaviorally in insects (Reichardt, W., 1961; Buchner, E., 1984), nonhuman primates (Krekelberg, B. and Albright, T. D., 2005) and humans (Anstis, S. M., 1970; Anstis, S. M. and Rogers, B. J., 1975). This behavioral evidence suggests that the pathways detecting bright (On) and dark (Off) onsets interact within the motion system and that this interaction has the signature of a multiplication.

Behavioral evidence in humans, however, suggests that the On and Off systems are not treated as symmetrically as envisaged in the Reichardt model. For instance, the direction of motion in a sequence of dark and bright flashes requires a much longer interstimulus interval to be detectable than a sequence of flashes of the same polarity (Wehrhahn, C. and Rapf, D., 1992). Moreover, the reverse-phi phenomenon is found for eccentric presentations, but is much reduced near the fovea or when the distance between the observer and the stimulus is increased (Lu, Z. L. and Sperling, G., 1999).

2.09.3.2.3 Phase invariance

The Reichardt detector determines the autocorrelation of an input signal. Because the autocorrelation does not depend on the starting phase of the signal, this implies that for any arbitrary pattern (that can be described as the sum of sinusoidal gratings), replacing one of the component gratings by a phase-shifted grating does not change the output of the detector. This prediction has been confirmed at the behavioral level in the beetle. Reichardt took two (essentially arbitrary) spatial patterns and constructed a first visual stimulus by simple addition of the patterns, and a second visual stimulus by adding the patterns with a spatial phase shift. When a beetle was confronted with these two visual stimuli, its walking behavior on the Spangenglobus was identical (Reichardt, W., 1961).

2.09.3.2.4 Pattern dependence

While the phase of gratings does not affect the output of the detector, other properties, such as the spatial frequency, do. This shows that the Reichardt detector is not ideal; its output is not the same for every visual stimulus with the same velocity. While suboptimal from the viewpoint of an ideal motion detector, this does provide another counterintuitive prediction of the Reichardt model. To be precise, the model predicts that for every speed the detector responds only weakly to the lowest spatial frequencies, climbs to a maximum, and then declines for higher spatial frequencies. Optomotor responses in many insects are consistent with this prediction (Buchner, E., 1984).

A more extreme case of mistaken velocity arises from spatial aliasing for high spatial frequencies. When a rightward Reichardt detector is stimulated with a rightward moving grating whose spatial period is smaller than twice the distance between the input channels it will evoke a negative (i.e., leftward) response. While this is clearly an undesirable property for a motion detector, the behavior of the blowfly actually matches this (Zaagman, W. H. *et al.*, 1976). In other insects, the relationship between the behavioral inversion and receptor spacing is not as clean, although this may be understood by assuming that the detector receives input from more than one neighboring ommatidium (McCann, G. D. and MacGinitie, G. F., 1965; Thorson, J., 1966b).

Human visual motion perception is also spatial frequency dependent in a manner that is consistent with the Reichardt model (Burr, D. C. and Ross, J., 1982; Smith, A. T. and Edgar, G. K., 1990). The inversion of the perceived direction of motion that is observed at high spatial frequencies in insects, however, is not observed in human behavior (van Santen, J. P. and Sperling, G., 1984). The simplest way to modify the Reichardt model such that the spatial aliasing no longer occurs is to remove the affected high spatial frequencies from the input at an early stage. van Santen J. P. and Sperling G. (1984) proposed the extended Reichardt model, which has such prefilters and removes the spatial aliasing behavior (see flow-chart in Figure 4). The presence of the prefilters reflects the fact that the elementary light sensors that provide input to the motion detectors are not point sensors, but have an (overlapping) spatial extent.

Interestingly, the pattern dependence in the Reichardt detector arises only at the last subtraction stage. The so-called half-detectors' response to a moving pattern is almost independent of its spatial frequency. In other words, they are velocity tuned and not spatiotemporal frequency tuned (Zanker, Z. M. *et al.*, 1999). But, as pointed out above, the motion selectivity of such half-detectors is weak (Borst, A. and Egelhaaf, M., 1990). In a biological system, it seems likely that the subtraction of a leftward and

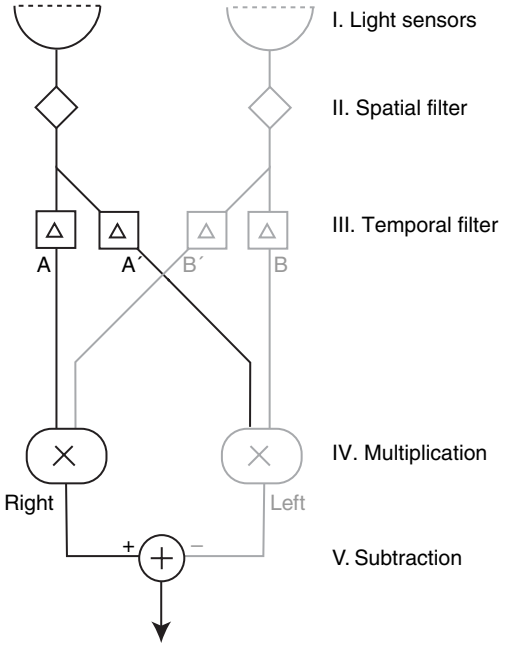

Figure 4 The extended Reichardt model. Light falling on the retina is spatially (II) and temporally filtered (III). The outputs of the four filters are then pairwise multiplied (stage IV). As in the standard Reichardt detector, the rightward-selective subunit (black) is combined with a mirror symmetric leftward-selective subunit (gray), at stage V.

rightward half-detector may not be perfect. This would have the effect of creating detectors that trade-off motion selectivity (fully symmetric subtraction at stage IV) against pattern invariance (no subtraction of opposite motion detectors).

2.09.3.3 Physiological Evidence

Many physiological studies have looked for and found neural response properties consistent with the Reichardt detector. Figure 5 shows what the model predicts for experiments that measure the space–time response map by presenting single flashes at various positions in a neuron's RF. The first four space–time response maps represent recordings from neurons at stage III of the extended Reichardt model (indicated by A, B, A′, and B′ in Figures 4 and 5). The defining property of these space–time RFs is that they are not oriented in space–time; they are well described as the product of a spatial and a temporal profile. This separability is also observed at stage IV; here both the left and the rightward subunit are predicted to have the same response to flashed stimuli. As a result, the complete detector, which subtracts the outputs of left and right detectors, gives no response at all to single flashes.

2.09.3.3.1 Facilitation and suppression

As can be seen from Figure 5, an ideal Reichardt detector should not respond at all to a single flashed bar. With an ingenious device that allowed them to flash a light on individual photoreceptors of the fly's eye while recording extracellularly from an identified direction-selective neuron (H1) in the optic lobe, Franceschini N. *et al.* (1989) provided evidence for this property. Single flashes, whether dark or bright, did not evoke a response in the H1 neuron. Such clean Reichardt behavior is rare; typically, motion detectors

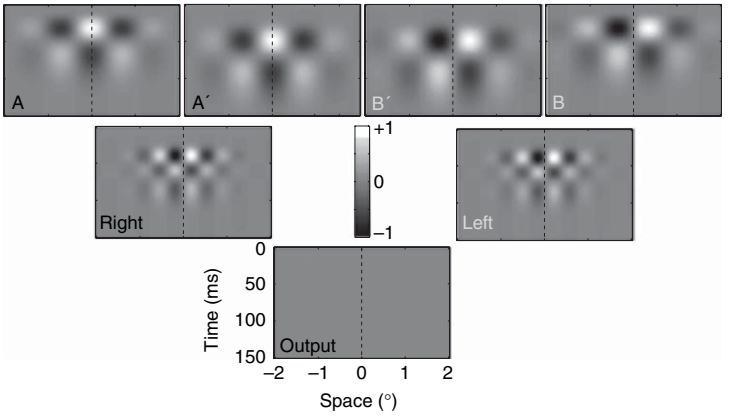

Figure 5 One flash space–time response maps of the Reichardt model. Each of these plots shows the response of a stage in the extended Reichardt model to the presentation of a single bright flashed stimulus. Time after the stimulus runs down the vertical axis, the position of the stimulus relative to the receptive field center, is on the horizontal axis. Pixels brighter than the gray zero level (see scale bar at center), represent an increase in the activity, dark pixels represent a decrease in activity. Within the linear model, such a decrease in firing after the presentation of a bright bar is equivalent to an increase in firing after the presentation of a dark bar. The labels in the lower left corner of each space–time response map refer to the labels in Figure 5.

will respond vigorously to a single flash (Borst, A. and Egelhaaf, M., 1990). No major modification of the model is required to explain this. For instance, some level of spontaneous activity in the multiplication stage would suffice to allow a strong input to always evoke a significant response. Alternatively, the subtraction of the left and right subunit outputs may not be perfect. For instance, instead of calculating R-L, the detector may calculate R-βL, where $0 < \beta < 1$ (Borst, A. and Egelhaaf, M., 1990).

The essential prediction of the Reichardt detector is that the response to two successive flashes – displaced in the preferred direction – is larger than that to two successive flashes displaced in the antipreferred direction. In other words, by comparing two-flash apparent motion in the preferred and antipreferred direction, one should observe facilitation and suppression of the neural response, respectively. Model calculations for this facilitation (bright) and suppression (dark) are shown for a rightward Reichardt motion detector in Figure 6.

Franceschini N. *et al.* tested this in the H1 neuron of the fly. When two successive flashes to separate photoreceptors simulated preferred motion, the second flash evoked a strong response (Franceschini, N. *et al.*, 1989). Presenting these flashes in the opposite order, simulating antipreferred motion, however, evoked no response or, in a cell with a large spontaneous firing rate, a suppression of the firing rate. This is consistent with the regions of facilitation (white) and suppression (black) around the origin of the interaction map in Figure 6. This was confirmed by Borst A. and Egelhaaf M. (1990) who recorded interaction maps for the fly H1 neuron. At low contrast, the preferred direction flashes showed clear facilitation, while the antipreferred direction flashes showed suppression. The suppression was evident also at high contrast, but the facilitation disappeared. The latter may be explained by a saturation process: if the individual flashes evoke a strong response, their combination in the preferred direction may not lead to any further enhancements because the response is already near the maximum and saturates. This, again, shows an imperfection in the neural motion detector. While the Reichardt detector predicts a quadratic increase of the response with contrast, real neurons do not have an infinite range and will saturate at some contrast level (Ibbotson, M. R. *et al.*, 1999). This is not a difficult property to incorporate into the model, but uncertainty about the shape of the contrast response function for all systems provides additional obstacles to the creation of a quantitative model.

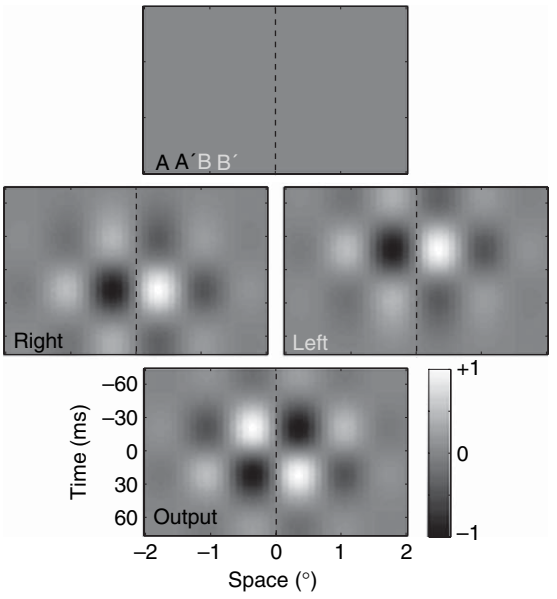

Figure 6 Two-flash space–time interaction maps of the extended Reichardt model. These interaction maps show which part of the response to two successive flashes is not expected based on the linear summation of the response to the two flashes presented in isolation. The time between the two flashes is on the vertical axis, the distance between the flashes on the horizontal axis. Bright pixels show a facilitating interaction, dark pixels a suppressive interaction.

In the rabbit retina, the main effect underlying DS appears to be a suppression for the antipreferred direction (Barlow, H. B. and Hill, R. M., 1963; Barlow, H. B. *et al.*, 1964; Amthor, F. R. and Grzywacz, N. M., 1993; Fried, S. I. *et al.*, 2002), with a smaller contribution from facilitation for two flashes presented in the preferred direction (Grzywacz, N. M. and Amthor, F. R., 1993; Taylor, W. R. and Vaney, D. I., 2002; Fried, S. I. *et al.*, 2005). This has led to the so-called veto model. In this model, the activity of a second flash, presented in the antipreferred direction, is inhibited (vetoed) by the presentation of the first flash. The requirements for this model are very similar to those of the Reichardt model. Notably, the first flash must be able to evoke suppression at a later time (i.e., a delay is needed). Later work has shown that a multiplicative nonlinearity may implement this veto mechanism (Torre, V. and Poggio, T., 1978; see Section 2.09.3.3.4).

2.09.3.3.2 Reverse-phi

The Reichardt model predicts that an inversion of the contrast of a two-flash stimulus leads to an inversion of directional preference.

Franceschini N. *et al.* (1989) investigated this by stimulating individual photoreceptors and found that there is more facilitation between flashes of the same contrast polarity than between flashes of opposite polarity. Thus they argue for some level of separation between the On and Off pathways. A later study, however, showed clear evidence of reverse-phi in the fly H1 cell: suppression is observed when a bright–dark two-flash stimulus is presented in the preferred direction, and facilitation is seen for a bright–dark two-flash stimulus presented in the anti-preferred direction (Egelhaaf, M. and Borst, A., 1992). While not entirely resolved, the discrepancy between these two studies may have been due to response saturation at the high contrasts used in the earlier studies. Alternatively, it could be due to the small sample size of the earlier studies (Franceschini, N. *et al.*, 1989; Horridge, G. A. and Marcelja, L., 1991) and the fact that there is considerable inter-fly variability between H1 neuron responses (Egelhaaf, M. and Borst, A., 1992).

In vertebrates a segregation of pathways processing brightness increments (On) and brightness decrements (Off) is already found at the first synapse; between photoreceptors and bipolar cells (Kuffler, S. W., 1953). The behavioral reverse-phi phenomenon, however, shows that the motion system must recombine these pathways at some stage. Indeed, the reverse-phi property has been observed in primary visual cortex (cat: Emerson, R. C. *et al.*, 1987; monkey: Livingstone, M. S. and Conway, B. R., 2003), subcortical motion pathways in marsupials (Ibbotson, M. R. and Clifford, C. W., 2001), and the cortical middle temporal area in the monkey (Livingstone, M. S. *et al.*, 2001; Krekelberg, B. and Albright, T. D., 2005).

2.09.3.3.3 Nonlinear interactions

The multiplication of two signals is the essential nonlinearity that creates DS in the Reichardt detector (Poggio, T. and Reichardt, W., 1973; 1981). Such a quadratic nonlinearity predicts that a sinusoidal input signal will lead to output signals that vary at the fundamental as well as the second harmonic frequency. To be specific, for a moving grating sliding over the detector, one can split the response of the detector into three terms. The first is time independent and changes sign with the direction of motion, the second term modulates at the temporal frequency of the stimulus, and the third term modulates at twice the frequency of the stimulus (Egelhaaf, M. *et al.*, 1989).

In an ideal Reichardt detector the oscillations in one subunit precisely cancel those in the other subunit. But, of course, precise cancellation is a mathematical abstraction that is not truly expected in biological hardware. When stimulated with a moving grating, direction-selective horizontal cells (HS) in the blowfly show oscillations. Nearly 90% of the signal was found at or below the second harmonic frequency. This shows that the nonlinearity in the HS motion detector is indeed close to second-order. Moreover, as predicted by the Reichardt model, the oscillations at the fundamental (stimulus) frequency depended strongly on the direction of the stimulus, but the frequency-doubled responses did not (Egelhaaf, M. *et al.*, 1989). This confirms that the Reichardt model provides a good description of the directional properties exhibited by the HS neuron, with the addition that the subtraction of the subunit outputs is not perfect. Typically, the gain of the antipreferred subunit is on the order of 0.9. This makes the motion detector suboptimal, because the equal subtraction of the two subunits maximizes DS (Borst, A. and Egelhaaf, M., 1990). Moreover, this imbalance will also cause vigorous responses to flickering patterns that do not move, but whose luminance is modulated over time. This is found for many motion sensitive neurons both in invertebrate (Egelhaaf, M. *et al.*, 1989) and vertebrate systems (Churan, J. and Ilg, U. J., 2002).

Interestingly, however, such imperfectly balanced and therefore suboptimal motion detection units have a reduced dependence on the spatial frequency of the stimulus. In fact, the response of a single subunit is tuned for velocity, and not temporal frequency (Zanker, Z. M. *et al.*, 1999). This suggests that some visual systems could use imperfect subunit subtraction (stage V, Figure 4) to trade-off optimal DS against spatial frequency dependence. One price to pay for imperfect subunit subtraction, however, is that in such a detector the direction-selective signal rides on top of a large nondirection-selective component. It is not clear under which circumstances the advantage of reduced spatial frequency dependence could outweigh this disadvantage of high energetic cost and reduced signal-to-noise.

2.09.3.3.4 Shunting inhibition

The Reichardt detector makes use of multiplication. This is a decidedly nonlinear mechanism and does not fit easily with the standard integrate and fire view of a neuron. When one takes a closer look at the biophysics of realistic neurons, however,

multiplicative nonlinearities appear to be possible by a mechanism called shunting inhibition (Thorson, J., 1966a; 1966b; Torre, V. and Poggio, T., 1978).

Consider a model neuron with an excitatory channel and inhibitory channel. The reversal potential for the excitatory channel is typically much larger than the resting potential; this provides the depolarizing current flow of an excitatory input. The reversal potential of the inhibitory channel, however, is assumed to be slightly above the resting potential. The two channels are organized such that preferred motion leads to temporally nonoverlapping activation of the channels. For a two-flash preferred direction stimulus this arrangement will lead to a depolarizing current from the excitatory channel as well as a depolarizing current from the inhibitory channel. In other words, the response to a two-flash sequence is somewhat higher than that to a one-flash sequence. Note, however, that this effect is a simple linear summation, and no difference is expected between the sum of the response to two single flashes and the response to two flashes, i.e. there is no nonlinear facilitation in this shunting inhibition model. While this may account for the limited facilitation found in direction-selective cells in the rabbit retina (Barlow, H. B. and Hill, R. M., 1963; Barlow, H. B. *et al.*, 1964), it is not a good model of the nonlinear facilitation observed in insects (Borst, A. and Egelhaaf, M., 1990).

When motion in the antipreferred direction is presented to the model shunting neuron, the excitatory and inhibitory conductances are activated at the same time. Under these circumstances the inhibitory channel essentially creates a large hole in the membrane. Any current flow caused by the simultaneous activation of excitatory channels will simply seep out through this hole. In other words, this so-called shunting inhibitory channel can veto nearby excitatory currents. A formal analysis shows that the efficacy of the veto is proportional to the product of the excitatory and inhibitory conductances (Torre, V. and Poggio, T., 1978). Hence, the suppressive part of the motion mechanism is similar to the multiplicative nonlinear element in Reichardt's original model. This example relies on a simplified model neuron, but Koch C. *et al.* (1983) developed a model that incorporates the spatial extent of the dendritic tree and the relative positioning of excitatory and shunting inhibition channels. They confirmed that shunting inhibition can lead to the desired veto-effect, but found that it will only veto excitatory input if the inhibitory conductance is located between the excitatory input and the soma. It should be noted, however, that in such a model with biophysically realistic assumptions the pure quadratic nonlinearity as envisaged in the Reichardt model is difficult to implement with shunting inhibition (Grzywacz, N. M. and Koch, C., 1987).

The shunting inhibition model provides a possible mechanism to implement a multiplicative nonlinearity, but what is the evidence that shunting inhibition is actually used in neural systems? Many direction-selective neurons contain gamma-aminobutyric acid (GABA) activated chlorine channels whose reversal potential is close to the resting potential. In other words, the GABAergic synapse could function as a shunt. Indeed, shunting inhibition has been demonstrated directly in cat visual cortex (Borg-Graham, L. J. *et al.*, 1998; Hirsch, J. A. *et al.*, 1998). Moreover, when GABAergic synapses are inactivated pharmacologically, DS in many systems is greatly reduced (fly: Schmid, A. and Bülthoff, H., 1988; rabbit: Ariel, M. and Daw, N. W., 1982; cat: Sillito, A. M., 1977). However, one should be cautious in interpreting this as evidence in favor of the shunting inhibition model. There are many stages in the Reichardt model that require some kind of inhibition. For instance, the subtraction stage (IV in Figure 3, V in Figure 4), subtracts the outputs of the two subunits. This subtraction removes nondirection-selective components from the subunits and helps create a strongly direction-selective motion detector (Borst, A. and Egelhaaf, M., 1990). If GABAergic synapses underlie this subtraction, then GABA antagonists would be expected to decrease DS, no matter how the multiplicative interaction were implemented.

In the fly, a clever experiment was done to distinguish such linear GABA-dependent contributions from nonlinear GABA-dependent contributions to DS. The crucial idea behind this experiment is that the multiplicative nonlinearity introduces higher harmonics in the output signal of the detector. The subtraction of the two subunits of the Reichardt detector, however, removes those components. In other words, by determining whether GABA agonists decrease or increase the higher harmonics, one can determine whether they affect the multiplicative or subtractive element of the Reichardt detector. Egelhaaf M. *et al.* (1990) showed that while GABA application decreased the overall DS of the H1 cell, the power of the second harmonic frequency increased nearly tenfold. This clearly shows that, if the H1 cell is indeed well-described by the Reichardt model, its multiplicative stage in the fly H1 cell is unlikely to be implemented with GABAergic shunting inhibition.

2.09.4 Space–Time Orientation

The view of motion as the successive activation of two detectors by the same feature may work well as the basis for the study of insect vision, and some artificial motion detection systems. In contrast, for vertebrates – and humans in particular – the distribution of detectors is nearly continuous and it is unclear which features need to be matched across which periods of time and between which detectors. Adelson E. H. and Bergen J. R. (1985) formulated a view of motion that deals with such problems and side-steps the correspondence problems associated with feature matching. They noted that a single bar, moving along a horizontal trajectory, can be represented as a slanted pattern in a space–time diagram (Figure 7(a)). Rightward slant implies rightward motion, and leftward slant leftward motion. Moreover, the slant angle in the pattern corresponds to the speed of the motion. The slant does not depend on the shape or features of the moving object; hence the correspondence problem essentially vanishes.

Moreover, in this view of motion, there is no fundamental difference between continuous motion and apparent motion. Figure 7(b) shows the space–time diagram that corresponds to the apparent motion that a bar in a modern neurophysiological experiment would typically trace out on a computer screen. A detector that detects the space–time slant corresponding to continuous motion would also respond to the slant associated with apparent motion. This is an appealing property of this view of motion; not only does it provide an intuitive explanation of the perceptual phenomenon of apparent motion (and hence why movies generate a sense of motion); it also validates the use of (apparent) motion on computer screens to study motion detection (Watson, A. B. *et al.*, 1986).

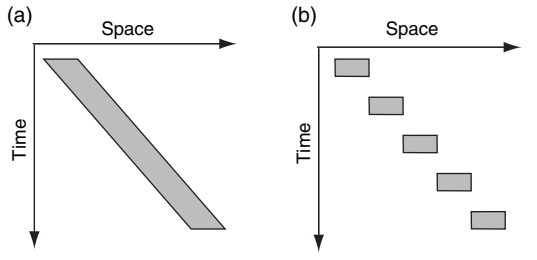

Figure 7 Motion as space–time orientation. (a) When a bar moves smoothly rightward over time, it traces out an oriented trapezoid in a space–time plot. (b) When that same bar jumps from one place to the next (apparent motion), the space–time orientation is still clearly visible.

2.09.4.1 The Motion Energy Model

Adelson E. H. and Bergen J. R. developed a multistage spatiotemporal filtering model that could detect space–time slant with neurophsyiologically realistic building blocks. The flow diagram of this so-called energy model is shown in Figure 8.

Each stage in this filtering model serves a specific purpose. The first stage collects light; it represents the photoreceptor input. The second stage filters the image spatially, with one of two spatial filters, shown in panel (b). In this particular example, the spatial filters are odd and even Gabor functions. The third stage filters the image temporally, using the filters shown in panel C. One filter's response is slower than the other, thus allowing the comparison of images at different times.

At the fourth stage, inputs from two separate pathways are summed linearly. In this particular example, the spatial and temporal filters were carefully chosen such that the fourth stage of the model would lead to slanted space–time filters. These particular filters are said to be in quadrature relationship (one filter reaches its peak when the other goes through zero; Watson, A. B. and Ahumada, A. J., 1985). While this relationship leads to the best sensitivity to motion, the only features that are essential to create space–time slant are the presence of a fast and a slow temporal filter, and spatial filters that prefer flashes in slightly different positions in space. Neurons at this stage modulate their response in a direction-selective manner, but their time-averaged response is independent of direction. This is a very general finding; a linear model cannot generate a time-averaged direction-selective output (Poggio, T. and Reichardt, W., 1973; 1981). Stage V represents the only nonlinear element in the motion energy model; it creates a signal whose time average is direction selective. At this point in the model the average response is direction selective, but the response of the neuron still depends on the position of the moving stimulus in the cell's RF. This so-called phase dependence is removed in stage VI by adding two detectors with slightly different spatial properties. Based on psychophysical data obtained in humans, Adelson E. H. and Bergen J. R. added the seventh stage to the model. At this stage, the rightward motion energy is subtracted from the leftward motion

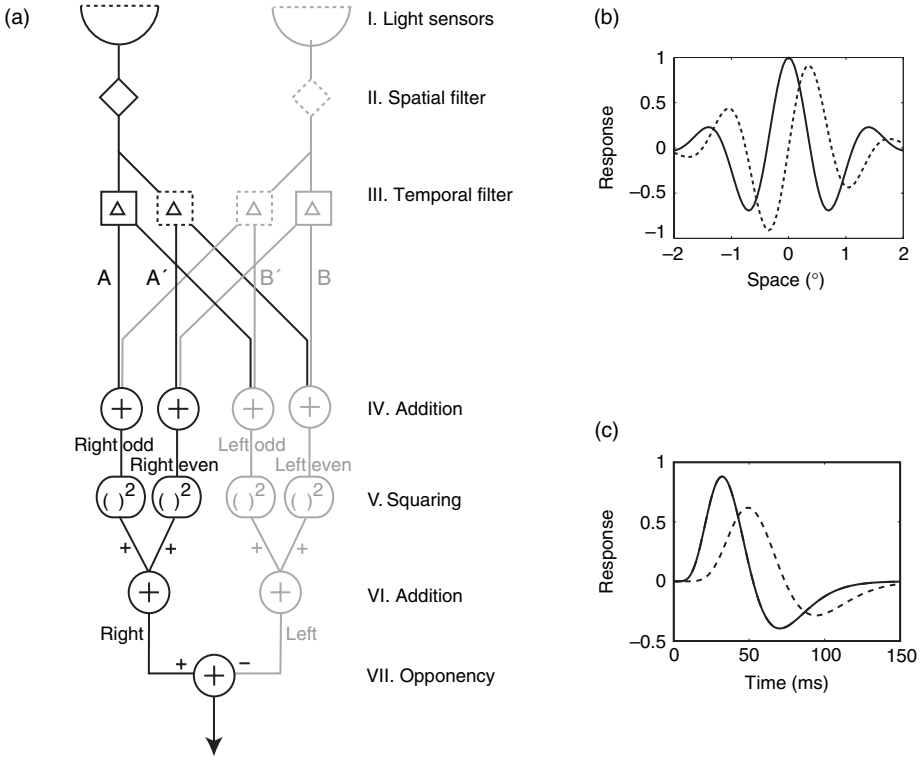

Figure 8 The motion energy model. (a) A chart of the signal flow in the model. In black are the components of the rightward-selective subunit, in gray the mirror symmetric leftward-selective unit. The diamonds at level II indicate spatial filtering with the filters shown in panel (b). Similarly, the temporal filtering of stage III uses the filters of panel (c). (b) Even (solid line) and odd (dashed line) spatial filters. (c) Fast (solid line) and delayed (dashed line) temporal filters.

energy to provide a single-valued output that represents the perceived direction. Positive values correspond to rightward motion, negative values to leftward motion.

The name motion energy arises from a consideration of the model in Fourier terms. In a Fourier spectrogram of the luminance distribution, opposite quadrants represent motion in the same directions. Hence, to create a detector that responds to rightward motion (quadrants I and III), one first has to remove the DC components along the spatial and temporal frequency axes. Stages II and III do this. Stage IV then selectively removes signal components from quadrants II and IV. Finally, the squaring operation of stage V measures the power or energy present in the remaining signal.

2.09.4.2 Behavioral Evidence

Given the different components in the model, it may be somewhat surprising that – at the output level – the (extended) Reichardt detector and the motion energy model are in fact identical (Adelson, E. H. and Bergen, J. R., 1985; van Santen, J. P. and Sperling, G., 1985). As only the output of the whole detector is typically observable behaviorally, psychophysical experiments cannot distinguish between these two models. This implies that the evidence cited in favor of the Reichardt detector in Section 2.09.3.2 equally supports the motion energy detector.

The internal algorithms of the detectors – how they reach their conclusion – however, are fundamentally different. Physiological methods can probe that internal implementation of motion detection mechanisms and are discussed in the next section.

2.09.4.3 Physiological Evidence

Simulations of the motion energy model make specific predictions about the properties of cells at various stages in the model. Figure 9 shows the predicted space–time response maps as assessed with one-flash stimuli. First, note that the structure of the motion–energy model at stage III (Figure 8) is identical to that of the Reichardt detector at stage III (Figure 4). Hence, the motion energy model also

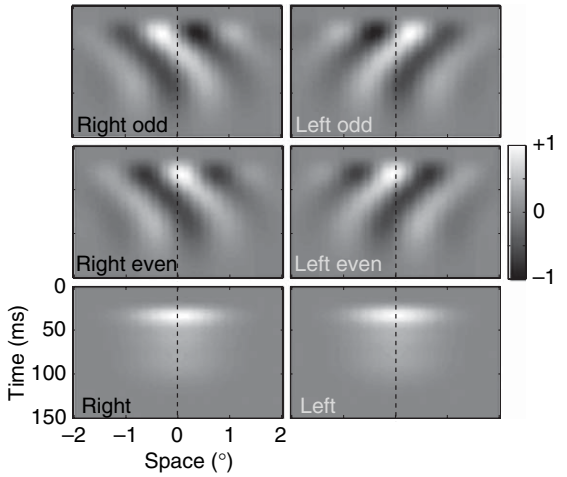

Figure 9 One-flash space–time response maps of the motion energy model. This figure follows the conventions of Figure 5. The space–time response maps of stage III of the motion energy model (A, B, A′, B′), are identical to those of the Reichardt model shown in Figure 6 and are not repeated here.

predicts the existence of cells with space–time response maps as shown for A, B, A′, and B′ in Figure 5. At stage IV, however, the models diverge. Figure 9 shows the characteristic slanted response maps expected at stages IV and VI of the motion energy model.

The various stages of the motion energy model can be mapped quite naturally onto the visual system of cats and primates. I will review the evidence for the various stages in sequence.

2.09.4.3.1 Input from the lateral geniculate nucleus

In cats and primates, few retinal or lateral geniculate nucleus (LGN) cells are direction selective, but many cells in primary visual cortex are (Hubel, D. H. and Wiesel, T. N., 1959; 1962). Hence, much of the research guided by the motion energy model has been devoted to determining whether a linear summation of the output of appropriate LGN cells can lead to a direction-selective response in the cortex.

Cai D. *et al.* (1997) probed cat LGN RFs with single flashes. They showed that the space–time RFs were typically not slanted. The space–time response maps resembled the outputs at stage III (A, B) shown in Figure 5. Note, however, that even though these LGN space–time response maps were not slanted, they were are also not separable. That is, their space–time response map could not be written as the product of a spatial impulse response function and a temporal impulse response function. For the discussion of motion detection, however, I will ignore this and approximate them by separable functions. Qualitatively this is a good approximation.

Stage IV of the motion energy model requires inputs that are delayed with respect to each other. In the LGN of the cat, the lagged and nonlagged cell classes seem to fulfill this prediction quite well (Mastronarde, D. N., 1987a; 1987b; Saul, A. B. and Humphrey, A. L., 1990; Cai, D. *et al.*, 1997). Primate LGN also has classes of cells that are delayed with respect to each other; the magnocellular cells typically give fast, transient responses, while parvocellular cells respond with a later sustained firing rate (Marrocco, R. T., 1976; Schiller, P. H. and Malpeli, J. G., 1978).

In the spatial domain, the inputs to the motion detector also need to be shifted; either in phase, or in space. A shift in phase, combining an odd and an even symmetric cell whose spatial RFs are in so-called quadrature, would be optimal (Figure 8(b)). Most cells in the LGN, however, have even symmetric spatial RFs; hence it will be difficult to construct an optimal motion detector from combining LGN cells. The motion energy detector, however, can also function with two RFs that are shifted spatially. Because LGN cells have RFs covering the whole visual field and because neighboring LGN cells are organized in a retinotopic fashion, collecting input from two LGN cells with slightly shifted spatial inputs should be relatively straightforward.

Given that appropriate input neurons exist in both cat and primate LGN, what is the evidence that these actually provide the input to the direction-selective cells of primary visual cortex? Certainly, both lagged and nonlagged cells project to the cortex, and simple cells – especially those in layer 4B – contain subregions of the RF in which response properties mimic those of LGN lagged cells and other subregions that match properties of nonlagged cells (Saul, A. B. and Humphrey, A. L., 1992). Moreover, some direction-selective (DS) simple cells have been shown to receive monosynaptic inputs from lagged LGN cells (Alonso, J. M. *et al.*, 2001). However, this does not necessarily mean that all DS cells must receive their input directly from the LGN. The alternative hypothesis is that the LGN projects to non-DS simple cells and these provide the input to DS simple cells.

There is evidence that at least some DS cells follow this indirect route. Peterson M. R. *et al.* (2004) recorded from pairs of monosynaptically

connected simple cells; one was DS, the other was not. For each cell in such a pair, they determined the space–time response map and then subtracted the RF of the non-DS cell from the RF of the DS cell. Given the linearity assumptions of the motion energy model, this should result in the RF of the missing second-input neuron. Peterson M. R. *et al.* show examples of DS simple cells in which the non-DS simple cell provides the late-input component. Because such a DS simple cell receives its delayed input from another simple cell, it does not have to rely on a lagged LGN cell. This shows that a direct input from lagged LGN cells is not necessary for DS.

Using these same methods, Peterson M. R. *et al.* also showed that there is a range of time delays between the two inputs of DS cells, and most are much smaller than predicted by the original motion energy model. In the original model, the inputs were in temporal quadrature (Figure 8(c)). While this relationship produces an optimal detector (Watson, A. B. and Ahumada, A. J., 1985), it is not necessary to create moderate DS. Taken together the evidence from the cat suggests that DS simple cells receive both direct lagged and nonlagged LGN input as well as input from other (non-DS) simple cells. The temporal delay between these inputs varies considerably across cells.

In monkey V1, De Valois and colleagues (De Valois, R. L. and Cottaris, N. P., 1998; De Valois, R. L. *et al.*, 2000) investigated the source of the input signals of DS simple cells by determining the temporal profile of the response in V1 simple cells. According to the motion energy model, this temporal profile should consist of the sum of two components; one delayed with respect to the other (Figure 8(c)). To extract these components, De Valois R. L. *et al.* used principal components analysis. First, they looked at non-DS cells. These cells typically had only a single significant component and there were two clearly distinct subsets. One set of cells had a profile with a short latency and a biphasic temporal profile; the other set had a longer latency and a monophasic profile. Then, they determined the response profiles of direction-selective cells. These cells had two significant input components, one matched the early biphasic profile, and the other matched the late monophasic profile of the non-DS cells. This strongly suggests that DS cells become direction selective by linear summation of the output of cells from the two distinct classes of non-DS simple cells (or their LGN inputs). Interestingly, the delay between the two temporal profiles corresponds closely to temporal quadrature, which suggests that these motion detectors are better optimized than those in the cat (Peterson, M. R. *et al.*, 2004). In the spatial domain, the relationship between the inputs was more varied and the optimal spatial quadrature relationship between the two inputs is expected to be rare.

The two temporal profiles observed in V1 simple cells correspond quite closely to the response properties of two anatomically identifiable subclasses of LGN cells. Magnocellular cells have short latencies and transient biphasic responses. Parvocellular cells have longer latencies and typically a monophasic sustained response. Hence, the view that arises from this work is that magnocellular and parvocellular LGN cells each have their own non-DS simple cell targets in V1. Other simple cells then sum the input from these non-DS simple cells to generate DS in the linear manner envisaged by the motion energy model.

This is controversial because anatomical, lesion, and psychophysical studies have all been used to argue that motion is processed by the magnocellular stream. Anatomical evidence shows that layer IVcα of V1 – where many DS cells are found – mainly receives magnocellular input (Blasdel, G. G. and Fitzpatrick, D., 1984). The counter argument is that there is also evidence showing strong vertical interactions within a column; hence even if the parvocellular properties cannot reach DS cells after crossing one synapse, they can after two. Second, lesion studies have been interpreted as showing a selective involvement of the magnocellular pathway in motion perception (Merigan, W. H. and Maunsell, J. H., 1993), but there are counter examples. Two studies have recorded from V1 cells while reversibly inactivating magnocellular and/or parvocellular layers in the LGN (Malpeli, J. G. *et al.*, 1981; Nealey, T. A. and Maunsell, J. H., 1994). These studies showed that many DS simple cells receive input from both classes of LGN neurons and that DS is often only abolished when both magnocellular and parvocellular inputs have been silenced. While this shows that a contribution of parvocellular cells to motion detection is certainly likely, it remains unlikely that the roles of the magnocellular and parvocellular cells in motion detection are as symmetric as in the de Valois model. For instance, lesions of the magnocellular layers of the LGN have a greater influence on the responses of direction-selective cells in the middle temporal area (Maunsell, J. H. *et al.*, 1990).

2.09.4.3.2 Linear summation

The previous section shows that signals with appropriate temporal and spatial shifts find their way into V1 simple cells. The next question is how these nondirection-selective inputs are combined. The motion energy model predicts linear summation of inputs.

Many studies using extracellular recordings from cat simple cells support this view. In a typical experiment, the RF of a neuron is mapped with one kind of stimulus (single flashes, stationary gratings) and then the response to another kind of stimulus (drifting sine wave gratings, or two successive flashes) is predicted based on the assumption of linear response properties. Qualitatively this was already done in the first studies of simple cells in the cat visual cortex (Hubel, D. H. and Wiesel, T. N., 1959) and found to account for the direction preference of some, but certainly not all cells. In later studies these statements have become more precise. It was found that the RF determined with flashes could predict quite well when a moving bar elicited the largest response (i.e., when moving from an Off to an On region). Other features, in particular the small response for motion in the antipreferred direction could not be predicted from linear superposition and various schemes of nonlinear lateral facilitation and inhibition were proposed (Goodwin, A. W. *et al.*, 1975; Emerson, R. C. and Gerstein, G. L., 1977a; 1977b; Ganz, L. and Felder, R., 1984). All of these studies, however, used extracellular recordings and they could not distinguish between nonlinear synaptic integration and nonlinear spike generation. Hence, these results left the possibility that all observed nonlinearities were in fact due to spike generation nonlinearities (Movshon, J. A. *et al.*, 1978b).

A new wave of studies in the late 1980s tested the linear model. Although the authors sometimes differed in their conclusions, with the benefit of hindsight their datasets actually appear quite similar. Most measured space–time response maps were slanted and corresponded with the motion energy model (Figure 9), but not with the separable response maps predicted by the Reichardt detector (Figure 5). These slanted space–time RF maps could usually predict the preferred direction of a cell, but underestimated the magnitude of the directional preference (Mclean, J. and Palmer, L. A., 1989; Tolhurst, D. J. and Dean, A. F., 1991; Reid, R. C. *et al.*, 1987; 1991; Baker, C. L., Jr., 2001). Albrecht D. G. and Geisler W. S. (1991) resolved this discrepancy by realizing that nonlinearities unrelated to DS itself, could nevertheless affect the predictions of the linear model. One nonlinearity they had recently measured was the contrast dependence of the neural response. They proposed a neural model in which linear summation of the inputs is followed by half-wave rectification and an exponential nonlinearity. The exponent of this nonlinearity could be derived from the contrast response function of the neuron. With this model, they could explain nearly 80% of the magnitude of the DS of simple cells and later studies have confirmed this (DeAngelis, G. C. *et al.*, 1993). While this model still leaves ~20% to be explained, this does not necessarily mean that the 20% are due to nonlinearities essential to the generation of DS. Instead this could be due to other contrast-related nonlinearities such as gain control (Heeger, D. J., 1992).

To really answer the question whether DS is based on linear summation, one needs to bypass the spike-generation nonlinearity. Jagadeesh B. *et al.* (1993; 1997) did this by recording intracellularly from cat simple cells. Their data provide clear evidence for three aspects of the motion energy model. First, DS simple cells sum their non-DS inputs linearly. This was shown by predicting the membrane potentials evoked by moving gratings from the linear superposition of the potentials evoked by stationary contrast modulated gratings. This prediction was highly accurate. Second, Jagadeesh B. *et al.* showed that the DS of the spike record (i.e. what would have been measured in extracellular recordings) was about three times larger than that observed in the intracellular recordings. This directly confirms the role of the spike-generation nonlinearity as an amplifier of DS (Albrecht, D. G. and Geisler, W. S., 1991; McLean, J. *et al.*, 1994). Third, they showed that nearly all of the membrane potential could be explained by the summation of inputs from only two subunits. These subunits had nonoriented space–time response maps (Kontsevich, L. L., 1995; Jagadeesh, B. *et al.*, 1997).

In a further test of the linear model, Priebe N. J. and Ferster D. (2005) measured separate space–time response maps of excitatory and inhibitory conductances in DS cat simple cells for bright and dark bars. First, all four response maps were clearly slanted; showing that both excitation and inhibition were direction selective for both dark and bright bars. Second, the slant in the excitatory and inhibitory maps was the same. Hence excitation and inhibition preferred the same direction of motion. This argues strongly against a vetolike mechanism for DS in these

cells, because such a model would predict an opposite direction preference for the inhibition. Third, when and wherever the excitation was maximal, inhibition was minimal. This suggests that DS is derived in a push–pull fashion; a bright bar in an On region of the RF evokes a depolarization (push) and a dark bar at the same position evokes a hyperpolarization (pull). When a stimulus moves across a RF, the pushes and pulls are evoked at different times and sum linearly. Finally, a nonlinear spike-generation mechanism removes subthreshold modulations and amplifies the relatively weak DS in the membrane potential (by a factor of 2–3; just above the squaring nonlinearity of the motion energy model). Together this creates a spike signal whose time-average is strongly direction selective (Priebe, N. J. and Ferster, D., 2005).

In the monkey, tests of the motion energy model have followed a similar path. Extracellular recordings showed slanted space–time response maps for DS simple cells (De Valois, R. L. and Cottaris, N. P., 1998; Livingstone, M. S., 1998; De Valois, R. L. *et al.*, 2000; Conway, B. R. and Livingstone, M. S., 2003). As explained above for cat simple cells, this is evidence against a Reichardt model. As was the case for cat simple cells, the space–time response map could predict the preferred direction of a cell, but it underestimated the magnitude of the DS (Conway, B. R. and Livingstone, M. S., 2003). To date, no intracellular recordings have been performed to determine whether the spike-generation nonlinearity underlies the enhancement of DS as it does in the cat (Jagadeesh, B. *et al.*, 1993).

2.09.4.3.3 Motion opponency

In the final step of the motion energy model, the output of a leftward motion-selective unit is subtracted from that of a rightward motion-selective unit. Behavioral evidence in humans shows that such an opponent stage must be present in the brain (Stromeyer, C. F. *et al.*, 1984). Given the description of DS simple cells in the previous section, it seems natural to ask whether complex cells, which are thought to combine input from multiple simple cells, implement this opponent stage of motion processing.

To test this hypothesis, Emerson R. C. *et al.* (1992) measured space–time interaction maps in cat complex cells. These maps show the nonlinear facilitation or suppression that one flash causes in the response of a second flash. Up until the squaring stage of the motion energy model, no nonlinear interactions are predicted, but at stage VI, simulations show that the

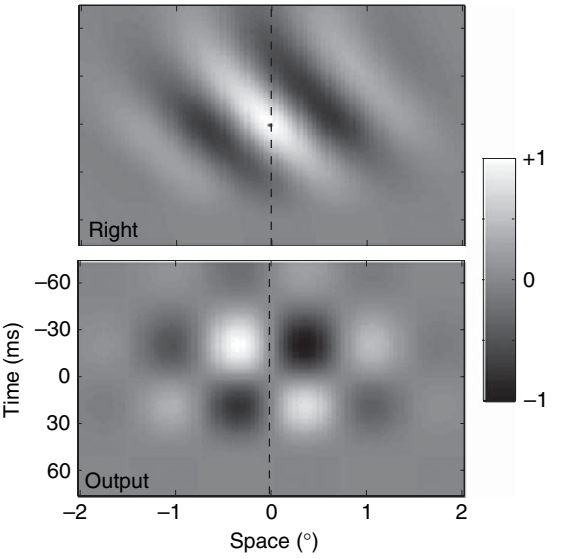

Figure 10 Two-flash space–time interaction maps in the motion energy model. This figure follows the conventions of Figure 6.

interaction maps should be slanted (Figure 10). At the opponent stage of the detector, on the other hand, the interaction maps should be separable (remember that the opponent stage is formally identical to the output of the Reichardt model, which has separable interaction maps at all stages). The evidence shows, however, that cat complex cells have slanted spatiotemporal interaction maps (Emerson, R. C. *et al.*, 1992; Touryan, J. *et al.*, 2002), which is incompatible with the motion-opponent stage. Moreover, in a direct test of motion opponency, van Wezel R. J. *et al.* (1996) demonstrated that complex cell responses are suppressed by a stimulus moving in the antipreferred direction, but this suppression is far from complete ($\sim$ 50%). In fact, the response to a stimulus consisting of two directions of motion is often well described by the average of the responses to the two directions of motion presented separately. These data suggest that complex cells are best described by stage VI of the motion energy model.

Macaque complex cells also have slanted interaction maps and, when combined with a squaring nonlinearity, account reasonably well for the DS to grating stimuli (Gaska, J. P. *et al.*, 1994; Livingstone, M. S., 1998; Conway, B. R. and Livingstone, M. S., 2003). As in the cat, this shows that they are well described by stage VI of the motion energy model but not the opponent stage. In agreement with this, macaque V1 cells also show

incomplete suppression for stimuli containing two opposing directions (Qian, N. and Andersen, R. A., 1994). Somewhat surprisingly, macaque complex cells not only have slanted interaction maps, but also slanted space–time response maps (Conway, B. R. and Livingstone, M. S., 2003). This is not expected in the motion energy model (Figure 9), although an imbalance between the subunits could cause this kind of response.

Finally, Livingstone M. S. (1998) showed that many macaque V1 complex cells had a spatially offset inhibitory zone on the null side of the RF. Such a zone is not expected in the motion energy model, but is reminiscent of the veto model of DS in the retina (Barlow, H. B. *et al.*, 1964). To recap, in the latter view a stimulus moving into the RF from the null side, produces a delayed inhibition that removes the fast excitation produced when the stimulus is in the center of the RF. Livingstone M. S. and Conway B. R. (1998; 2003) speculated that such delayed asymmetric inhibition could arise from an asymmetric dendritic tree. If such a tree has slow inhibitory inputs near the soma, and fast excitatory inputs on the asymmetric dendritic tree, then a stimulus moving in the antipreferred direction (from soma to dendrites) would evoke overlapping excitation and inhibition and therefore lead to little activation. For a stimulus moving from the dendrites toward the soma, on the other hand, the excitatory input would reach the soma and evoke spikes before the somatic inhibition could stop it. Anderson J. C. *et al.* (1999) investigated this hypothesis by a combination of physiology, anatomical reconstruction of single neurons, and modeling. First, they showed that the asymmetry of a dendritic tree did not predict cells' preferred direction. Second, their compartmental model showed that the delays that can be generated within a typical single dendritic tree were too short to explain sensitivity to slow motion. This suggests that the contribution of asymmetric inhibition to DS in the monkey is small.

The main projection area of DS complex cells in the macaque is the middle temporal area. Many of these cells reduce their response below the spontaneous firing rate when stimulated in the antipreferred direction (Maunsell, J. H. and Van Essen, D. C., 1983; Albright, T. D., 1984). While this shows the presence of some opponent mechanisms, there is no clear evidence for an opponent stage as it is postulated in the motion energy model. First, space–time interaction maps in MT are slanted, and not space–time separable (Livingstone, M. S. *et al.*, 2001; Pack, C. C. *et al.*, 2006). Second, even in MT the suppression of the response to a preferred stimulus by an antipreferred stimulus is far from complete (Snowden, R. J. *et al.*, 1991; Qian, N. and Andersen, R. A., 1994). Rather than a linear subtraction of opponent responses, the interaction of multiple directions of motion may be described more accurately as a (nonlinear) competition among multiple spatial and temporal frequency components (Krekelberg, B. and Albright, T. D., 2005).

When considering how MT cells can be constructed from their V1 (and LGN: Nassi, J. J. *et al.*, 2006) inputs, it is important to keep in mind that some motion tuning properties change considerably between V1 and MT. This is the case even if we consider only MT component cells and not the even more complex MT pattern cells (see Chapter Cortical Mechanisms for the Integration of Visual Motion). For instance, MT cells are much more invariant to changes in the stimulus pattern (Albright, T. D., 1992), MT cells integrate motion over longer periods of time (Mikami, A. *et al.*, 1986), the preferred speed of MT cells is typically higher than that of V1 cells (Mikami, A. *et al.*, 1986; Churchland, M. M. *et al.*, 2005), and MT cells are more speed-tuned than temporal frequency-tuned (Perrone, J. A. and Thiele, A., 2001; Priebe, N. J. *et al.*, 2003; Perrone, J. A., 2006; Priebe, N. J. *et al.*, 2006). It is difficult to see how such differences can arise from the simple linear operations envisaged in the motion energy model. The issues concerning speed tuning may be resolved in a model by Perrone and Thiele. In this model, MT cells combine inputs from typical transient and sustained V1 cells in a nonlinear manner, which generates sensitivity to higher speeds and speed tuning that is invariant to stimulus pattern (Perrone, J. A. and Thiele, A., 2001; 2002; Perrone, J. A., 2005). Some of the features of this model (e.g., using transient V1 cells to estimate temporal stimulus gradients) are similar to space–time gradient models; the next section discusses such models in detail.

2.09.5 Space–Time Gradients

Models building on the principle of space–time gradients start from the observation that spatial and temporal change must coincide in an image to produce motion. This insight leads to a measure of

velocity in an image (I) that is defined as the ratio of the temporal and spatial change:

$$V(x, t) = \frac{(\partial I/\partial t)}{(\partial I/\partial x)}$$

Mathematically, this measure defines the true velocity at every point in space and time. This is quite different from the outputs of the Reichardt and motion energy detector, which do not signal the same velocity for every spatial pattern (see Section 2.09.3.2.4). Moreover, because a contrast change will affect both the numerator and the denominator of the gradient model, the velocity estimate does not depend on the contrast of the image. In other models, such contrast-invariance is commonly built-in after motion estimation by processes of normalization and gain control (Heeger, D. J., 1992). Mathematically, therefore, this model truly is a better estimator of velocity. The question is, however, whether this estimate is used by the brain.

The biggest challenge for the model is that velocity becomes ill-defined in regions where the spatial gradient is zero. A number of solutions have been proposed to circumvent this problem. For instance, one can first find regions with spatial change (edges) and only then determine the ratio in a second processing stage (Marr, D. and Ullman, S., 1981). Other alternatives are to include higher-order spatiotemporal derivatives – one of which will likely be nonzero (Johnston, A. *et al.*, 1992), or to pool velocity estimates over space – the estimate will be well defined for at least some positions (Heeger, D. J. and Simoncelli, E. P., 1994).

The elementary computation required in this model is differentiation. While at first somewhat difficult to imagine, differentiation is easy to implement with simple neural elements. Consider a standard On center neuron. Its output can be described as the weighted sum of its inputs. If we assume the RF is a bell-shaped function (for instance a Gaussian), we can write its output as G^*I, the weighted sum of the image with the RF. The gradient model requires outputs that are related to dI/dx, for instance G^*dI/dx. Because this neuron's output is linear, the order of the weighted sum and differentiation operations does not matter: $G^*dI/dx = dG/dx^*I$. In other words an output proportional to the derivative of the image can be obtained from a simple linear neuron whose RF is shaped like the derivative of a bell-shaped function. Higher-order derivatives can be computed using increasingly complex RF structures (Koenderink, J. J. and Van Doorn, A. J., 1987). Looking at the spatial filters in the motion energy model (Figure 8) they are reasonably well described as each other's derivatives. The same is true for the temporal filters. In other words, the motion energy model implicitly relies on spatial and temporal derivatives. By reformulating the models, it can actually be shown that some variants of the gradient models are formally equivalent to motion energy models (Heeger, D. J. and Simoncelli, E. P., 1994; Bruce, V. *et al.*, 2003).

2.09.5.1 Behavioral Evidence

Given that some gradient schemes are formally equivalent to correlation and energy schemes for restricted classes of stimuli, it is difficult to distinguish among these schemes using behavioral methods. In line with this, Johnston A. *et al.* (1992) have demonstrated that many motion phenomena that have been interpreted in favor of the space–time correlation or orientation schemes, such as reverse-phi, are also found in their variant of the gradient scheme.

An attractive property of the gradient model, which is not found in the other schemes, is that it accounts quite naturally for some second-order motion percepts (Johnston, A. and Clifford, C. W., 1995a; Johnston, A. *et al.*, 1999; Benton, C. P. *et al.*, 2001). Correlation or energy-based schemes need to hypothesize a separate rectification stage for the processing of second-order motion (Chubb, C. and Sperling, G., 1988; Cavanagh, P. and Mather, G., 1989; Chubb, C. and Sperling, G., 1989).

In a perfect gradient model, the velocity estimate does not depend on the spatial frequency of the visual pattern. As discussed in Section 2.09.3.2.4, however, both insect and human motion perception do depend on the stimulus pattern. Similarly, the gradient model predicts no stimulus contrast dependence, but behavioral data in humans clearly show a strong effect of contrast on speed estimates (Thompson, P., 1982; Krekelberg, B. *et al.*, 2006b). It is not clear whether an imperfect implementation of the gradient scheme could account for these known imperfections in motion perception.

2.09.5.2 Physiological Evidence

Johnston A. (1992) has proposed a biologically plausible way to implement the gradient scheme in the

biological hardware of primary visual cortex. Johnston's solution to the problem of ill-defined velocities in image regions without luminance change is to determine a series expansion of the image. The best least-squares estimate of the velocity is then given by:

$$V = T/S$$

$$T = \frac{\partial^2 I}{\partial x^2}\frac{\partial^2 I}{\partial x \partial t} + \frac{\partial^3 I}{\partial x^3}\frac{\partial^3 I}{\partial^2 x \partial t} + \cdots + \frac{\partial^n I}{\partial x^n}\frac{\partial^n I}{\partial^{n-1} x \partial t}$$

$$S = \frac{\partial^2 I}{\partial x^2}\frac{\partial^2 I}{\partial x^2} + \frac{\partial^3 I}{\partial x^3}\frac{\partial^3 I}{\partial x^3} + \cdots + \frac{\partial^n I}{\partial x^n}\frac{\partial^n I}{\partial x^n}$$

Each term in T and S can be implemented with differentiating filters of second and higher order. Figure 11 shows a few representative examples of the space–time response maps that this gradient model would require. Just as the response maps of the Reichardt detector, none of these are oriented in space–time. Clearly, there is no lack of such simple cells in primary visual cortex (Livingstone, M. S. 1998; Conway, B. R. and Livingstone, M. S., 2003) and they could provide the input to a gradient motion detector. Hence, in principle, the required filters seem to be present in visual cortex. However, as discussed in Section 2.09.4.3.2, many direction-selective simple and complex cells have space–time oriented response maps; those cells match the components of the motion–energy model, but they do not seem to have a place in the gradient model.

The gradient model has not received as much physiological attention as the other models. The reason for this may be that the behavioral evidence suggests that motion perception is not as perfect as the gradient model predicts. In the fly, however, the gradient model was explicitly compared to the Reichardt detector and the data clearly speak in favor of the latter. To wit, both the spike output (Egelhaaf, M. *et al.*, 1989) and dendritic calcium concentrations (Haag, J. *et al.*, 2004) of the direction-selective fly H1 neuron show clear nondirection-selective modulations that follow the intensity modulations of the input. Moreover, both response measures are tuned for a particular temporal frequency and not a true velocity (Pattern dependence; see Section 2.09.3.2.4). These imperfections in the H1 neuron indicate that it does not use the gradient scheme to detect motion. Similarly, it has been shown that the speed tuning of neurons in the macaque middle temporal area strongly depend on contrast (Krekelberg, B. *et al.*, 2006b) and it is known that these neurons are closely linked to the animal's speed percept (Liu, J. and Newsome, W. T., 2005; Krekelberg, B. *et al.*, 2006a). This contrast dependence would not be expected in a motion detection mechanism that relies on the ratio of spatial and temporal gradients.

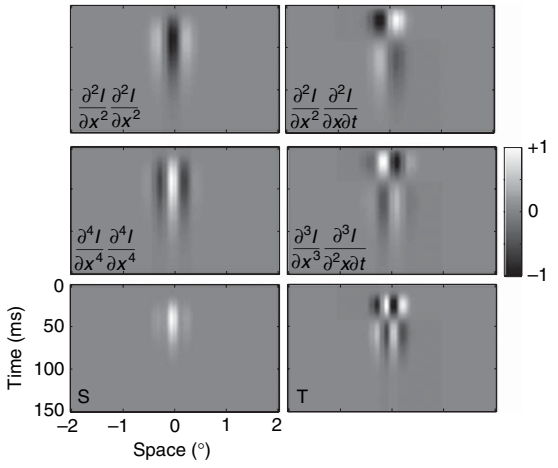

Figure 11 One-flash space–time response maps of the gradient model. This figure shows some of the differentiating filters that are required in the gradient model of Johnston, A. *et al.* (1992). Conventions as in Figure 5.

2.09.6 Conclusion

While motion itself is not a complicated phenomenon, motion detection by neural systems certainly is. The reason is that motion can be detected in so many different ways. Many of those detection mechanisms will not be perfect, but they may be good enough for a particular purpose. For instance, while the gradient model may balk at the imperfections of a motion energy detector, such details may not be important when deciding whether to stay put or flee an approaching predator. This view of motion detection – as a problem with many good but suboptimal solutions – suggests a less absolutist approach to the study of motion mechanisms.

Simulations of a perfect Reichardt, motion energy, or gradient-based model may appear to make strict and testable predictions, but small deviations from the ideal model can lead to significant changes in those predictions. The first factor to consider here is noise. Estimating RF properties such as space–time response maps and interaction maps with extracellular recordings is time consuming and even then results in relatively noisy estimates. For instance, a significant amount of noise could make the separable space–time

response map of a Reichardt detector look like the slanted space–time response map of the motion energy detector. Figure 1 illustrates the basic space–time filtering properties of the three models in a similar format. Without much difficulty, the motion energy filters can be seen as a blurred version of the Reichardt filters. Similarly, with enough measurement noise, the filters of the gradient scheme would be indistinguishable from those of the motion energy model. This shows that, due to their low signal-to-noise and the confounding influence of the unknown spike-generation nonlinearity, extracellular recordings alone may not be enough to really distinguish among these models. At the very least it shows that a small number of positive examples for a given model will not be enough to accept it. Intracellular recordings – with their ability to bypass the spike-generation nonlinearity – have revealed a surprising degree of linearity in the early stages of motion detection. It would be very interesting to see what these methods can reveal about later stages of motion detection such as the motion opponent responses in complex cells in the cat and cells in the middle temporal area of the macaque.

Apart from measurement noise, the possibility of an imperfect implementation of a motion detection scheme should also be taken into account. These imperfections sometimes lead to testable predictions (Borst, A. and Egelhaaf, M., 1990), but they can also blur the lines between the models. For Figure 12, I simulated an (extended) Reichardt detector that receives its input not from odd and even Gabor spatial filters (as in Figure 4), but from two even Gabor functions with a small spatial shift. The interaction map at the level of the leftward motion subunit shows elements that are oriented in space–time, one of the supposedly identifying markers of the motion energy model. Certainly, the space–time slant of this simulated imperfect Reichardt detector is much less clear than that of Figure 10, as well as that measured in detail in a complex cell in the cat (Emerson, R. C. *et al.*, 1992), but it shows that the lines between the models are not as clear as one might like.

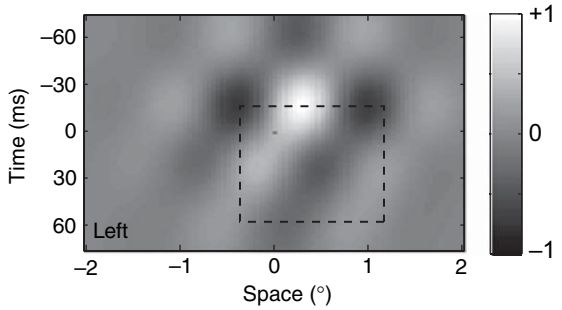

Figure 12 An imperfect Reichardt model. This space–time interaction map was calculated from an extended Reichardt detector in which the two spatial inputs are both even symmetric, but they are shifted such that the spatial receptive fields still have significant overlap. This overlap creates space–time slant in the area indicated by the dashed rectangle. Conventions as in Figure 6.

One can look at this issue from a quite different point of view. For the neuroscientist, models that are difficult to distinguish are a problem; they make the scientific story harder to follow and the conclusion less forceful. From the point of view of the brain, however, multiple models with similar prerequisites may be advantageous. Consider Figure 1 again; it shows that once the essential filters for a Reichardt detector are in place, building a motion energy detector should be relatively easy. Similarly, a slightly different combination of the same filters used for the motion energy detector could function as a gradient model. This suggests that the brain may not use motion detection mechanisms based exclusively on correlation, orientation, or gradients. Instead, multiple mechanisms could contribute at the same time and side-by-side. Although such mixing of multiple mechanisms does not appeal to the modeler with a keen eye for mathematical beauty, it may be the ugly reality of the perception of motion.

Acknowledgments

2.10.1 Introduction

Motion is one of the most important submodalities of vision, and specialized mechanisms to analyze movement are ubiquitous among visual creatures. Perceptually, there is good evidence that motion is a primary visual attribute like color, even though it is not directly available on the sensory epithelium as color is. Motion requires calculation, which makes the neural substrates of motion analysis particularly fruitful for study. The history of the study of motion analysis has benefited from a synergy between computational, physiological, and perceptual approaches.

Visual motion arises from the independent motion of objects in the visual environment or from the motion of the observer or a receptor surface – the retina, and frequently from both at once. Figure 1 shows a typical visual scene for a moving observer. This scene contains a multiplicity of moving objects, each with many contours. But all the retina receives is a complex time- and space-varying luminance pattern, from which we must reconstruct the physical causes, in order to generate appropriate behavior. This is not as simple as it first appears, for at least a couple of reasons. First and foremost, motion occurs in three dimensions, and the retina reduces this to a two-dimensional image. Second, other factors besides object motion can lead to time-varying luminance patterns on the retina – most notably changes in illumination – and the visual system must distinguish these from the real thing. Last, occlusion of one object by another or transparent motion can leave

Figure 1 Soccer World Cup 2006. Shows multiple objects, which move in three dimensions for the typical observer.

very complex patterns of local motions on the retina. So, the problem for motion analysis, as for many other visual calculations, is to take this raw, often ambiguous local data and calculate (or infer, as Helmholtz emphasized) the object and scene motions. It is not yet known how the visual system accomplishes this, but many parts of this problem are becoming fairly well understood. It is becoming increasingly clear that numerous operations at both local and global levels are happening in parallel at different levels of the motion system.

Most theoretical accounts of motion analysis are hierarchical in nature, and it comes as little surprise that there is also a hierarchy for processing motion in the cortex of primates – which is the focus of this chapter. In our description of the biology of motion processing, we will follow the functional logic of this hierarchy, which starts at a small spatial scale and ends at a large (global) spatial scale. Our point of view will be dominated by the physiology, but we will attempt to draw parallels to anatomy and computation whenever possible.

Not surprisingly, the central pathway implicated in motion analysis is also arranged hierachically. This pathway consists of a number of connected cortical areas, beginning in primary visual cortex. The defining property of these areas is the presence of directional selectivity. All areas in the figure have cells that signal the direction of moving stimuli in their firing rates, though in some of these areas only a fraction of neurons display this property. What we are emphasizing here, though, is the progressive change in the spatial scale of motion processing, from very local operations early in the cortical hierarchy through to very large-scale representations at the highest levels of the system. As we follow this pathway, we will attempt to capture what is known of the operations at each level, while also describing what remains unknown.

2.10.2 Local Motion Mechanisms: V1

2.10.2.1 Simple Cells and Linear Motion Mechanisms

Motion processing begins with local operations that detect the progression of image contrast across space and time. Local feature motion is best portrayed in a space–time diagram, of which several examples are shown in Figure 2.

What stands out in these figures is the presence of space–time orientation. Just as the analysis of stationary contours requires matched, orientation-selective receptive fields (RFs), the analysis of local motion requires RFs that are oriented in space and time (Poggio, T. and Reichardt, W., 1973; Borst, A. and Egelhaaf, M., 1989). Neurons with this property have been found early in the visual systems of a wide range of species, including insects (Egelhaaf, M. and Borst, A., 1993; Srinivasan, M. V. *et al.*, 1999; Ibbotson, M. R., 2001), birds (Frost, B. J. *et al.*, 1990; Wolf-Oberhollenzer, F. and Kirschfeld, K., 1994), reptiles (Fleishman, L. J., 1986; Wilke, S. D. *et al.*, 2001), fish (Wartzok, D. and Marks, W. B., 1973), and of course mammals (Ibbotson, M. R. *et al.*, 1994; Taylor, W. R. and Vaney, D. I., 2002). Motion processing in rabbits is particularly well studied, as they possess numerous

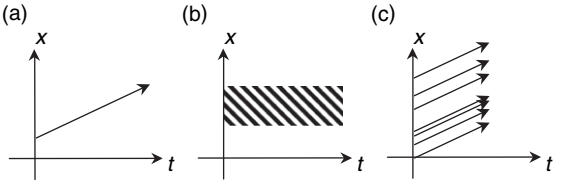

Figure 2 Space–time diagrams plotting an object's equation of motion $x(t)$, which is its spatial location as a function of time. (a) This diagram gives a visual picture of a bar's motion, with each point on the line representing both a location (collapsed across y) and a time. The straight line illustrated represents uniform motion, i.e., the object is moving at a constant speed. The slope of the line is equal to the velocity of the object at that moment. This object is moving rightward along x. (b) Space–time diagram for a moving grating, and (c) a coherently moving dot field.

direction-selective retinal ganglion cells (Barlow, H. B. *et al.*, 1964; Barlow, H. B. and Levick, W. R., 1965). As we focus on cortical mechanisms, this subject is outside our scope, and the reader is referred to recent reviews on the subject (Taylor, W. R. and Vaney, D. I., 2003; Poznanski, R. R., 2005).

In the well-studied geniculocortical pathway of the monkey, local motion detectors are first prominent in area V1, so we will focus on this area first. David Hubel and Torsten Wiesel (1962) recorded responses from striate neurons during the presentation of visual stimuli (moving bars of light) to the RF. In 1981, they won a Nobel Prize for their description of cells in V1 that respond preferentially to particular orientations or directions of movement. An example of a V1 simple cell, selective for both orientation and direction (DS), is shown in Figure 3. This cell is a simple cell, as evidenced by the distinct subregions of the RF responsive to bright and dark stimuli (green and red, respectively).

One key proposal from the work of Hubel D. H. and Wiesel T. N., which has largely been supported by decades of experimental testing, is the presence of a processing hierarchy through primary visual cortex. It is self-evident that RFs such as that shown in Figure 3 must be constructed from simpler (nonoriented) precursors. The key property evident in this RF is its slant, which can be phrased more accurately as space–time inseparability. What this term captures is that the temporal dynamics of the cell depend on the spatial location; this is what gives the slant to the RF. This property could emerge, in principle, from simpler subunits either in the direct input from the LGN or from other cortical neurons.

Figure 4 places the neuron shown in Figure 3 into a hierarchy of processing. Figure 4(a) shows an example of a nondirectional and nonorientation-tuned LGN neuron, which is quite similar to the RF of the nondirectional (space–time separable) simple cell in Figure 4(b). The similarity of the two RFs is allowed by the fact that these figures collapse across the two dimensions of space, concealing the orientation selectivity of the simple cell in Figure 4(b).

Numerous experiments have tested the adequacy of such linear mechanisms for producing the directional responses of simple cells to moving stimuli. In general, the approach is to use the superposition of successive stationary stimuli to predict the response to a moving stimulus (Reid, R. C. *et al.*, 1987; McLean, J. and Palmer, L. A., 1989; Reid, R. C. *et al.*, 1991; Jagadeesh, B. *et al.*, 1993; Livingstone, M. S., 1998). McLean J. and Palmer L. A. (1989) and Reid R. C. *et al.* (1991) found that the slant in the spatiotemporal RF correlated well with the DS and speed tuning of the cells. Thus, for these neurons, simple linear mechanisms can produce a good account of their directionality. However, while the linear mechanisms predicted the sign of the directionality and the speed tuning rather well, there was typically an underestimation of the magnitude of the directionality of the cells. Specifically, the response to motion in the nonpreferred direction seemed to be suppressed below the linear prediction (Reid, R. C. *et al.*, 1987).

The neuronal circuitry underlying the space–time inseparable RF remains unknown, but at least two

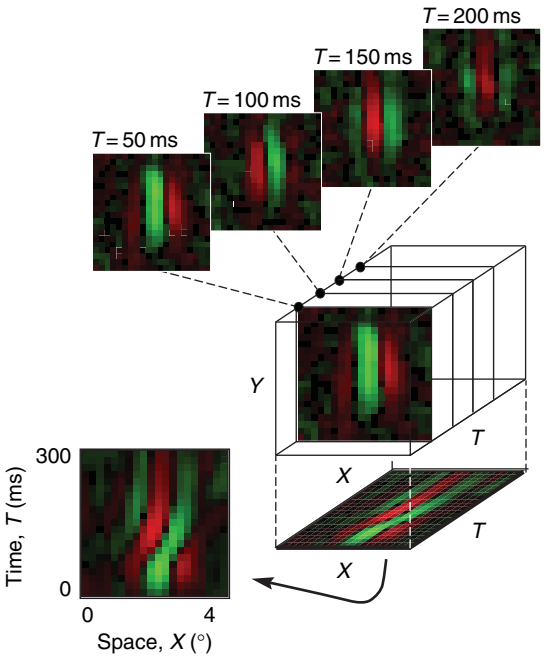

Figure 3 Example of a neuron tuned for orientation in both space and time. The map is formed by presenting white noise stimuli, and averaging to reveal what locations and times effectively trigger spiking. This procedure reveals the linear RF of a visual neuron. The horizontal axis is space (0–4°), vertical axis is time (0–300 ms), going backward in time. Time zero is at the bottom. This cell prefers leftward motion, because of the slant of the subregions in space and time. A contour or grating moving from right to left will first trigger long-latency responses, which can then sum with the shorter-latency responses from points farther to the left, if the stimulus is moving at a speed matched to the slant of the RF. See Reid, R. C., Soodak, R. E., and Shapley, R. M. 1991. Directional selectivity and spatiotemporal structure of receptive fields of simple cells in cat striate cortex. J. Neurophysiol. 66, 505–529. Copyright DeAngelis, G. C., Ohzawa, I., and Freeman, R. D. 1993. Spatiotemporal organization of simple-cell receptive fields in the cat s striate cortex. I. General characteristics and postnatal development. J. Neurophysiol. 69, 1091–1117.

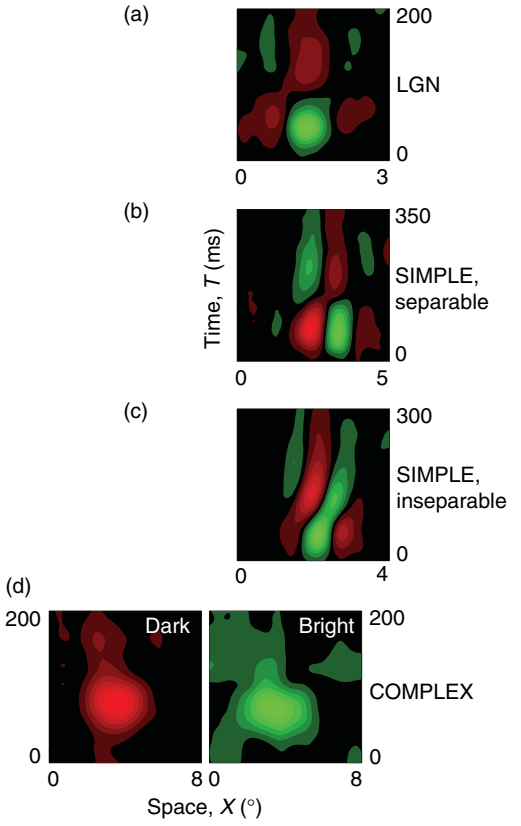

Figure 4 Spatiotemporal receptive field (RF) profiles (*X–T* plots) for neurons in the lateral geniculate nucleus (LGN) and V1 of the cat. The RF has been collapsed along the *Y*-axis. Subregions shown in green and red represent excitation to bright (ON) and dark (OFF) stimuli, respectively. (a) An *X–T* profile for a typical ON center *X*-cell from the LGN. The center and surround reverse sign at T > 50 ms. (b) An *X–T* profile for a simple cell with a space–time separable, not directionally selective, RF. For *T* > 100 ms, each subregion reverses polarity, so that the ON subregion is now on the left. (c) The same simple cell for which two-dimensional spatial profiles are shown in Figure 3, with a clearly inseparable *X–T* profile. Note how the spatial arrangement of ON and OFF subregions (i.e., the spatial phase of the RF) changes gradually with time. Note that the subregions are tilted in the space–time domain. The directional selectivity of this cell is leftward. (d) *X–T* profiles are shown for a complex cell. Responses to bright and dark stimuli are shown separately because these regions overlap extensively. From DeAngelis, G. C., Ohzawa, I., and Freeman, R. D. 1995. Receptive-field dynamics in the central visual pathways. Trends Neurosci. 18, 451–458.

possibilities exist. For both, there is a need to provide input to the directional cell from inputs that are slightly offset in space, with one slightly delayed in time relative to the other. Neurons tuned for different speeds could be constructed by employing inputs separated by different amounts in space and time. Theory suggests that if two inputs are in use – and most models are built this way to be tractable – they should be arranged in spatial and temporal quadrature (Watson, A. B. and Ahumada, A. J., Jr., 1983), which is a formalism for a quarter-cycle offset in both space and time.

Saul A. B. and Humphrey A. L. (1990) have identified two classes of X cells in the LGN of the cat, termed lagged and nonlagged, which have slightly different response latencies, close to this theoretical ideal. They have proposed that these two classes provide the necessary input timing delays to produce directional simple cells in striate cortex.

Another circuit possibility for directional simple cells is that the space–time inseparable RF is constructed from cortical inputs with suitable spatial and temporal separation, rather than directly from geniculate inputs. In monkeys, there is less agreement that separate populations of lagged and nonlagged LGN neurons exist. However, magnocellular (M) and parvocellular (P) LGN neurons might supply appropriate timing differences to subpopulations of V1 neurons (De Valois, R. L. *et al.*, 2000; Conway, B. R. and Livingstone, M. S., 2003). The fast biphasic responses of the (M) V1 cells and the slower monophasic responses of the P V1 cells differ in temporal phase by about a quarter of a cycle and could underlie direction selectivity. Direction selective V1 simple cells could combine the signals from subpopulations of non-DS V1 cells, which differ in their origins, either (M) or (P). In a similar vein, it has been argued that (M) neurons are not all purely transient, that some show sustained responses, and these could combine together to produce direction selectivity (Saul, A. B. *et al.*, 2005). In addition, a pair of separable (nondirectional) simple cell RFs might have even- and odd-symmetry (approximate spatial quadrature) and different temporal delays, to provide the correct inputs. One specific proposal is illustrated in Figure 5. Note the relatively rapid dynamics of the right-hand input, and the spatial phase difference between the two (Peterson, M. R. *et al.*, 2004).

2.10.2.2 Nonlinear Motion Mechanisms

While the linear, oriented RFs of simple cells can be directionally selective, the bulk of directional neurons are not well described by such simple models. Three broad classes of nonlinearity have been proposed, and direct evidence for each of the three has been found. First, divisive nonlinearity can be used to veto responses to nonpreferred motion. This sort of

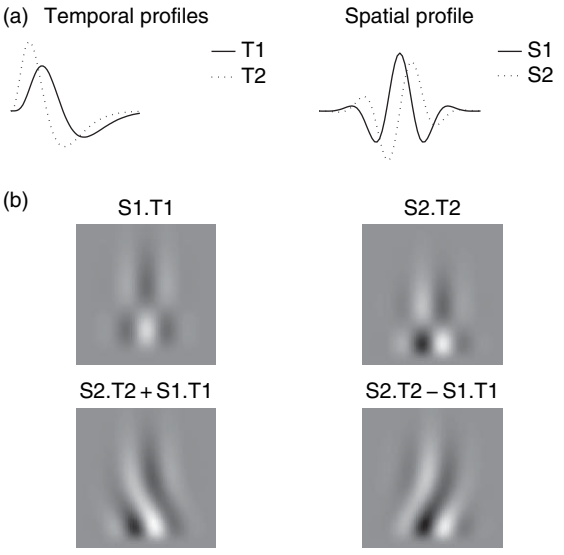

Figure 5 (a) Spatial (S1, S2) and temporal (T1, T2) filters that can be combined to produce (b) a linear motion sensor. The first stage of the linear motion sensor consists of spatiotemporal filters, each of which is the product of one of the two spatial filters and one of the two temporal filters. Space–time plots of the spatiotemporal sensitivity profiles of the two filters are shown in the upper part of (b), labeled S1, T1 and S2, T2. From Derrington, A. M., Allen, H. A., and Delicato, L. S. 2004. Visual mechanisms of motion analysis and motion perception. Annu. Rev. Psych. 55, 181–205.

operation appears to underlie the directionally selective responses of rabbit retinal ganglion cells (Hildreth, E. C. and Koch, C., 1987). Second, multiplicative operations can be used to facilitate preferred direction responses. This kind of model is consistent with the well-studied directional responses underlying optomotor responses in insects (Borst, A. and Egelhaaf, M., 1989; Egelhaaf, M. and Borst, A., 1993), and is mathematically described by a correlation operation (Hassenstein, B. and Reichardt, W., 1956). Last, a squaring operation is at the heart of motion energy models for directionality. Because this kind of operation is commonly related to the responses of directionally selective complex cells in cortex, we will primarily focus on this last class of model.

2.10.2.3 Complex Cells and Motion Energy

The defining feature of a complex cell, which differentiates it from a simple cell, is the absence of distinct RF subregions (see Figure 4(d)). For a grating stimulus, simple cell responses depend on the spatial phase of the stimulus, so that maximum response occurs when the bright parts of the stimulus are aligned with the on-region of the RF. In contrast, complex cells do not have RF subregions, making them insensitive to the phase of the stimulus, and they will respond to an appropriately oriented bar or grating anywhere within the RF.

Importantly, where simple cells linearly combine local responses, complex cells do so nonlinearly (Hubel, D. H. and Wiesel, T. N., 1962; Movshon, J. A. *et al.*, 1978). One significant nonlinearity is rectification – responses to both increments and decrements of illumination, leading to frequency-doubled responses to sinusoidally modulated stimuli, and approximately constant (DC) responses to drifting gratings. However, this is less important for directionality than nonlinear interactions between multiple stimuli within an RF. Direction selectivity is not evident in the appearance of the complex cell RF as it is in a simple cell, and is only revealed by experiments where two stimuli are allowed to interact within the RF. Such a second-order RF is obtained by probing the nonlinear interactions between two bars as they occur in relatively different positions and times within the RF. Figure 6 illustrates the regions in the RF where the responses depart from the expected linear sum of the first-order responses, and reveals both suppressive and facilitatory interactions. The second-order RFs are elongated, and oriented spatiotemporally, with the slope matching the cell's preferred direction and speed.

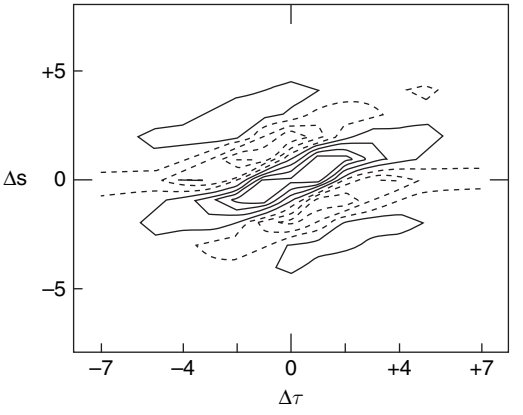

Figure 6 A second-order (nonlinear) receptive field profile, obtained from a mapping experiment with two bars present: a reference bar and a test bar. The responses to the test bar are plotted relative to what they would be absent the presence of the reference bar. The dashed contour lines denote negative regions of the interaction. From Emerson, R. C., Citron, M. C., Vaughn, W. J., and Klein, S. A. 1987. Nonlinear directionally selective subunits in complex cells of cat striate cortex. J. Neurophysiol. 58, 33–65.

Generally, this sort of RF is consistent with the predictions of a family of related motion models (Adelson, E. H. and Bergen, J. R., 1985; Heeger, D. J., 1987; Watson, A. B., 1987), all of which contain essential nonlinearities. The most commonly used is the motion energy model of Adelson E. H. and Bergen J. R. (1985), whose structure is illustrated in Figure 7. Its predictions, however, converge with those of Reichardt-style correlation models under most circumstances (van Santen, J. P. H. and Sperling, G., 1985). Where correlation models and motion energy models have been tested head-to-head (Emerson, R. C. *et al.*, 1992), the data tend to favor the motion energy model.

As is the case for directional simple cells, direct evidence for the local circuit that bestows directionality on DS complex cells is scant. This is unfortunate, since the various models make explicit (if somewhat abstract) predictions for cortical wiring, which are subject to direct experimental test. This is supported by the finding that simple cells in layer 4 project strongly to complex cells in layers 2 and 3 (Pollen, D. A. and Ronner, S. F., 1981; Field, D. J. and Tolhurst, D. J., 1986; Martinez, L. M. and Alonso, J. M., 2001). Many of these simple cells demonstrate the necessary range of spatial phases to produce quadrature pairs and motion energy detection.

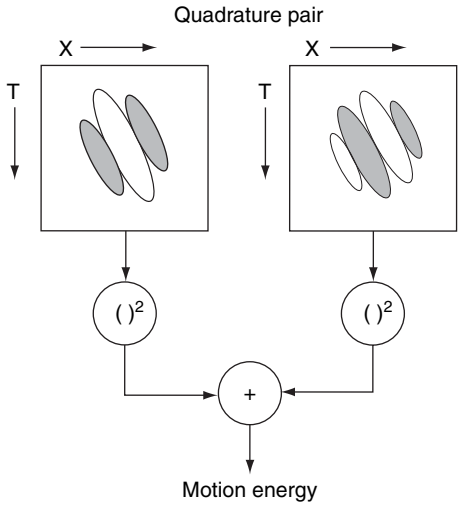

Figure 7 Simplified motion energy model. Note that one receptive field is odd-symmetric while the other is even. The outputs of the filters are squared and then added together to produce the motion energy. Each filter is phase dependent, with rightward direction selectivity. In comparison, the motion energy is phase invariant, with rightward direction selectivity. Reprinted from Adelson, E. H. and Bergen, J. R. 1985. Spatio-temporal energy models for the perception of motion. J. Opt. Soc. Am. A 2, 284–299.

2.10.2.4 Circuitry Underlying Local Motion Processing

The M pathway, as it arises from the LGN, is specially designed to be sensitive to moving stimuli. The parasol ganglion cells in the retina carry high contrast sensitivity, temporally acute, yet spatially coarse information to the M layers of the LGN (Enroth-Cugell, C. and Robson, J. G., 1966; Leventhal, A. G. *et al.*, 1981). This M information enters V1 in a segregated manner by synapsing in layer 4C. The most direct route this information can take through V1 is very short, via a monosynaptic connection between layer 4Cα and spiny stellate neurons in layer 4B that project directly to dorsal visual areas, particularly MT (Sawatari, A. and Callaway, E. M., 2000; Yabuta, N. H. *et al.*, 2001). Apart from this route, the transmission and integration of M information becomes more complex. In particular, while the input to the spiny stellate cells in layer 4B appear dominated by an M pathway connection from layer 4Cα, large pyramidal cells in layer 4B, which receive mixed M and P input also project to MT, though indirectly (Yabuta, N. H. *et al.*, 2001). This provides more sensitivity to form and color information then the M pathway alone could, and helps the animal to see what is moving.

In addition, M cells in layer 4Cα make synapses in layer 2/3 in conjunction with many color and form sensitive P cells, resulting in some degree of convergence (Lund, J. S. and Boothe, R. G., 1975; Callaway, E. M. and Wiser, A. K., 1996). Also, M cells project to layer 6 and synapse onto local type Iα cells and larger Meynert cells (Briggs, F. and Callaway, E. M., 2001). Layer 6 is one of the more directionally selective layers, and these cells may encode very specific columnar orientation and direction information (Hawken, M. J. *et al.*, 1988; Ringach, D. L. *et al.*, 1997). Though the local nature of their processes may be spatially restricted, the type Iα cells could synergistically work with the Meynert cells, which have broader dendritic fields, and may sum directional information across greater spatial distances, and project directly to area MT (Valverde, F., 1985). These α cells also provide feedback connections to layer 4Cα and may modify the inputs of this layer. Finally, layer 5 projects to the superior colliculus and the pulvinar, which has many directionally

selective neurons and provides an alternative route to area MT (Bender, D. B., 1982; Maunsell, J. H. R. and Van Essen, D. C., 1983a; Krubitzer, L. A. and Kaas, J. H., 1990; Dumbrava, D. *et al.*, 2001).

Complex cells, which often show strong direction selectivity, are found in greater numbers in layers 4B, 2/3, 5 and 6, all layers with strong M input (Hubel, D. H. and Wiesel, T. N., 1968; Hubel, D. H. *et al.*, 1976; Michael, C. R., 1981). Direction selectivity appears to emerge in neurons in upper layer 4 and layer 6 (Hubel, D. H. and Wiesel, T. N., 1968; Hubel, D. H. *et al.*, 1976; Michael, C. R., 1981; Blasdel, G. G. and Fitzpatrick, D., 1984; Livingstone, M. and Hubel, D., 1984; Hawken, M. J. *et al.*, 1988; Leventhal, A. G. *et al.*, 1995).

It was once believed that P and M inputs remained largely segregated in V1, which would enable outputs to separate areas or compartments to retain their characteristics (Livingstone, M. S. and Hubel, D., 1988). Instead, as Figure 8 illustrates, it now appears that P, M, and koniocellular inputs to V1 become mixed before their output to V2 (Sincich, L. C. and Horton, J. C., 2005) but see (Briggs, F. and Callaway, E. M., 2005). The functional consequences

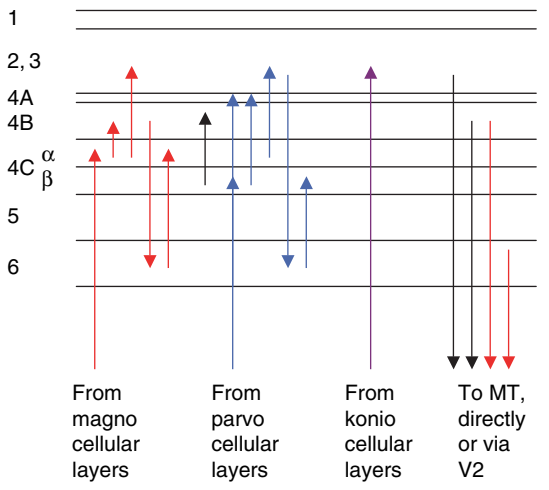

Figure 8 The segregation and integration of magno, parvo, and konio pathways through V1. The connections dominated by a class of input, magno (red), parvo (blue), or konio (purple) are drawn to highlight the segregation of signals in V1 and to MT. In addition, connections that integrate magno, parvo, and konio signals on the way to MT are illustrated in black. Most of the output from layer 2/3 goes to area V2, where it is further mixed, with some continuing to MT from there. A direct connection from the koniocellular layers in lateral geniculate nucleus to MT has also been described.

of this anatomical mixing are still unclear, however. Blocking responses in the M layers of the LGN nearly eliminates responses in MT (Maunsell, J. H. *et al.*, 1990), suggesting that the outputs from V1 toward MT remain largely unmixed. In contrast, substantial S-cone input appears evident in the chromatic sensitivity of both M LGN (Chatterjee, S. and Callaway, E. M., 2002) and in MT responses. Since S-cone inputs are dominant in the koniocellular pathway, this suggests a selective mixing of koniocellular and M signals; the consequences of this mixing for directional selectivity remain mysterious. Last, there is yet another opportunity for crosstalk between the parallel pathways in both feedback from higher cortical areas (e.g., V4) and in connections with accessory subthalamic nuclei, such as the pulvinar.

2.10.2.5 The Spatial Scale of Local Motion Operations

The spatial extent of directional selectivity has long been a fruitful platform for directly relating physiological and anatomical properties to perceptual phenomena. Motion psychophysics has a long history of quantifying the limits of perception, and this can be quantitatively related to the properties of different cortical areas. Examination of the spatial limits of direction discrimination provided one of the early uses of random noise displays, or kinematograms (random dot kinematograms). These are useful tools because they isolate local, or short-range motion mechanisms, which are perceptually very distinct from long-range apparent motion (Braddick, O. J., 1980). When a field of dots is displaced from one frame to the next, and if it exceeds a certain critical distance, then the direction of the displacement becomes perceptually ambiguous. This critical distance (D_{max}) was originally estimated to be about 15 arc minutes for central vision (Braddick, O., 1974). This corresponds fairly well with the dimensions of V1 RFs in the fovea. Furthermore, D_{max} scales with retinal eccentricity in a manner consistent with the scaling of RF sizes in V1 (Baker, C. L., Jr., and Braddick, O. J., 1982; 1985). This correspondence was directly examined by Mikami A. *et al.* (1985), and found to be remarkably precise.

These results are normally interpreted in the context of the Reichardt correlation model (Hassenstein, B. and Reichardt, W., 1956), illustrated in Figure 9. This class of models is conceptually the easiest to relate to

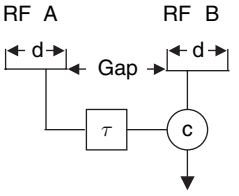

Figure 9 The Reichardt unidirectional bilocal correlation detector. The correlator (c) has delayed (τ) input from the detector at receptive field (RF) A and direct input from the detector at RF B. The psychophysically measured limits of motion detection can place meaningful values on both the size of the gap and the time delay (τ) between the detectors. Adapted from van den Berg, A. V. and van de Grind, W. A. 1989. Reaction times to motion onset and motion detection thresholds reflect the properties of bilocal motion detectors. Vision Res. 29, 1261–1266.

psychophysical measurements because the distance between the two local luminance-sensitive elements will directly predict the spatial limits of directionality; it fails when the extent of the displacement exceeds the distance between the detectors. Formal testing of the limits of perception in the context of this kind of model has proven very revealing (van den Berg, A. V. and van de Grind, W. A., 1989; van de Grind, W. A. *et al.*, 1992). From this whole body of work, a strong case can be made that directionally selective neurons in V1 are the primary, limiting location where the direction of object contours is calculated.

Another means to examine the spatial properties of motion processing is in the frequency domain. Because of the nature of Fourier analysis, the actual locations of the detectors are obscured, but their underlying filter properties are highlighted. Again, because these filter properties have been extensively studied in cortex, one can make quantitative comparisons between physiology and psychophysics.

Directionally selective neurons in V1 (and V2) prefer a wide range of spatial and temporal frequencies, but with a bias toward lower spatial frequencies and higher temporal frequencies (Foster, K. H. *et al.*, 1985). Under nonpreferred temporal frequencies, direction selectivity is reduced or even reversed in V1 (Saul, A. B. and Humphrey, A. L., 1992). Likewise, motion perception can reverse at high (or low) temporal frequency (Purves, D. *et al.*, 1996). This occurs because motion discrimination is band-pass for temporal frequency (Derrington, A. M. and Henning, G. B., 1993; Gegenfurtner, K. R. and Hawken, M. J., 1995), which matches perception with tuning properties in V1. Importantly, the timing properties of lagged and nonlagged cells in LGN are affected by temporal frequency in a manner consistent with these changes in direction selectivity.

2.10.2.6 Extrastriate Local Motion Processing

While V1 (Van Essen, D. C. and DeYoe, E. A., 1995) assumes legitimate importance as the first site of directional computations in cortex, motion processing occurs in a large number of connected cortical areas. The so-called motion system of dorsal extrastriate cortex is illustrated in Figure 10. The diagram indicates both hierarchical (serial) and parallel organization in this pathway. Connections from V1 fan out to multiple areas as they ascend the cortical processing hierarchy. Despite this fact, the literature of motion processing emphasizes only three areas, connected in series: V1, MT, and MST. However, the parallel ascending pathways to higher areas no doubt have considerable importance, though they have yet received very little study.

The most obvious change that occurs as one ascends the hierarchy is of RF size. This can be approximated as a doubling of RF diameter with each level beyond V1. Thus, V2 RFs are approximately twice the

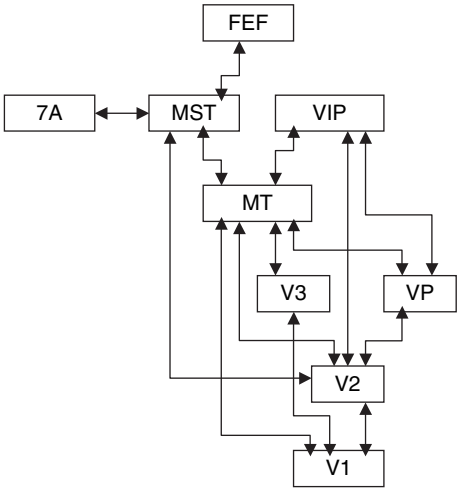

Figure 10 Major cortical areas in the motion system or pathway. Connection arrows are double headed to represent reciprocal connectivity between areas. Connections between the dorsal motion processing system and the ventral object-processing pathway exist, but are not illustrated here for clarity. These are the primary known connections; others may also exist. FEF, frontal eye feilds; MST, middle superior temporal area; MT, middle temporal area; VIP, ventral intraparietal area; VP, ventral posterior area.

dimensions of V1, V3 are around four times the dimensions, and MT about eight times the dimensions. This increase in spatial scale arises because of the pattern of divergent and convergent connections between connected cortical areas (Van Essen, D. C. *et al.*, 1986; Maunsell, J. H. R. and Van Essen, D. C., 1987; Amir, Y. *et al.*, 1993).

The functional relationship between these areas is probably best revealed by the increasing prevalence of direction selectivity. Direction selectivity is found in about 15% of V2 cells, and these occur mainly in the thick stripes (Levitt, J. *et al.*, 1994). Tracer studies show that roughly two-thirds of all V2 input comes from V1 (Sincich, L. C. and Horton, J. C., 2003). Layer 4B is one of the main inputs to the thick stripes in V2, and predominantly carries motion signals via a M stream (Shipp, S. and Zeki, S., 2002). However, there is evidence that novel response properties emerge in V2 as well. It is also the first area where a significant number of cells show directional responses to so-called second-order motion stimuli (Leventhal, A. G. *et al.*, 1998). These stimuli contain motion defined not by moving luminance contrast, but by the motion of regions defined by changes of contrast, flicker, or other higher-order image properties. The motion of such stimuli is highly visible to human observers, but do not trigger directional responses in either linear motion filters or in motion energy filters.

Strong direction selectivity occurs in 40% of area V3 cells, making it second only to MT in motion sensitivity. Area V3 receives both M- and P-dominated inputs, and projects to both MT and V4. While more than half the cells show some direction selectivity, most of the cells in layer 4, receiving V1 and V2 input, do not have such directional responses. Therefore, it is hypothesized that directional selectivity is developed *de novo* within V3 (Gegenfurtner, K. R. *et al.*, 1997). By studying the responses of directional cells to plaid patterns, Gegenfurtner K. R. and colleagues (1997) found that many V3 cells respond to the pattern motion of a plaid stimulus, much as area MT does. In addition, many motion responsive cells were also color sensitive, and respond directionally to isoluminant moving gratings. The significant integration of motion and color signals in V3 would be of practical use in dynamic form processing.

Regarding the function of area V3, differences between the neuronal properties and cytoarchitecture of areas V3d (also called DM) and V3v suggest that they constitute separate functional areas (Rosa, M. G. and Manger, P. R., 2005). Because of this, these areas may be redesignated, with area V3v becoming the newly redefined V3. V3d has a separate topographic representation of the visual field and appears much more directionally selective than V3v. More thorough research into this area's function in motion processing is required, but preliminary studies indicate a role in integrating motion signals, possibly for dynamic form analysis and figure-ground segregation (Felleman, D. J. and Van Essen, D. C., 1987; Gegenfurtner, K. R. *et al.*, 1997; Zeki, S. *et al.*, 2003).

Finally, both V2 and V3 receive extensive reciprocal connections with motion processing area MT (Van Essen, D. C. and DeYoe, E. A., 1995), which probably provides important feedback to functionally influence these earlier areas in their analysis of moving stimuli, whether defined by luminance (first order) or contrast (second order).

2.10.3 Medium Scale Motion Processing: Area MT

2.10.3.1 Anatomy and Connections

MT stands for middle temporal, the location where it was originally discovered in the owl monkey (Allman, J. M. and Kaas, J. H., 1971). Allman J. M. and Kaas J. H. (1971) found a retinotopically organized area that responded best to moving bars. At the same time, Dubner R. and Zeki S. M. (1971) discovered the homolog in the macaque monkey, located on the posterior bank of the superior temporal sulcus, which they named V5. Following this, many studies confirmed the location of MT as a well-defined area with dense myelination, receiving direct input from V1, and containing a high concentration of direction-selective neurons (Van Essen, D. C. *et al.*, 1981; Maunsell, J. H. R. and Van Essen, D. C., 1983b; Albright, T. D. *et al.*, 1984). Since its original discovery, this area has attracted tremendous interest and is probably better understood than any other extrastriate visual area. This interest arises from a number of factors, chief among them being the vigor and homogeneity of its directional responses.

As seen in Figure 11, MT lies near the middle of the dorsal stream and integrates inputs from a large number of areas. The cortical connections to MT are well understood, and come from V1, V2, V3, V3A, VP, V3d, and PIP (Maunsell, J. H. R. and Van Essen, D. C., 1983a; Felleman, D. and Van Essen, D., 1991). The most important input into MT, however, is from layer 4B of V1, as illustrated by the thickest arrow. This input is highly specialized, containing large diameter

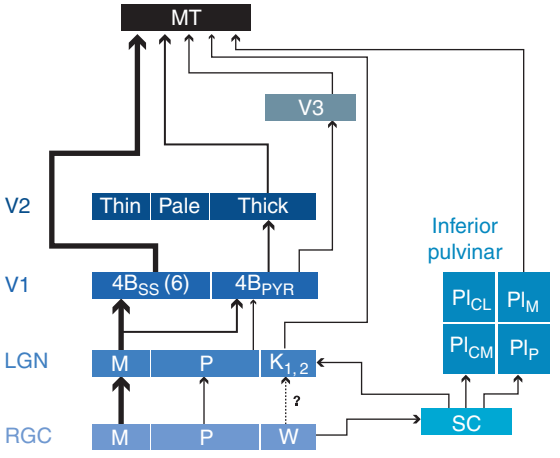

Figure 11 Major routes into MT in the manner of Felleman D. and Van Essen D. (1991). Line thickness is roughly proportional to the magnitude of the inputs. The thickest lines represent the direct cortical pathway emphasized in the text. The pathways shown omit a number of known feed-forward cortical inputs that appear lesser in magnitude (V3A, VP, PIP) as well as many subcortical inputs. The precise nature of the retinal inputs to K1,2 is not known, though their response properties are W-like in the galago Irvin, G. E., Norton, T. T., Sesma, M. A., and Casagrande, V. A. 1986. W-like response properties of interlaminar zone cells in the lateral geniculate nucleus of a primate (*Galago crassicaudatus*). Brain Res. 362, 254–270. $4B_{SS}$, spiny stellate neurons in layer 4B; $4B_{PYR}$, pyramidal neurons in layer 4B; LGN, lateral geniculate nucleus; M, magnocellular stream; P, parvocellular stream; K, koniocellular layers of LGN; PI_{CL}, central lateral nucleus of the inferior pulvinar; PI_{CM}, central medial nucleus of the inferior pulvinar; PI_{M}, medial nucleus of the inferior pulvinar; PI_{P}, posterior nucleus of the inferior pulvinar; RGC, retinal ganglion cells; SC, superior colliculus; VP, ventral posterior area. axons (up to 3μm), which form multiple synapses onto an MT neuron (Rockland, K. S., 1989). Physiologically, the majority of these MT-projecting neurons are directionally selective complex cells (Movshon, J. A. and Newsome, W. T., 1996). In addition to its cortical connections, MT receives input from subcortical areas: the superior colliculus, inferior pulvinar, and a small subset of koniocellular neurons in the LGN (Stepniewska, I. *et al.*, 1999; Sincich, L. C. *et al.*, 2004).

2.10.3.2 Physiological Properties and Functional Organization

The defining property of MT is its directional selectivity. Approximately 80–90% of MT neurons are strongly directionally selective. Figure 12 shows the response of a typical single MT neuron to a bar moving through its RF. Tuning bandwidths average about 50–60° by most estimates (half-width at half-height, or the nearly equivalent sigma of a fit Gaussian (Maunsell, J. H. R. and Van Essen, D. C., 1983b; Albright, T. D. *et al.*, 1984; Britten, K. H. *et al.*, 1996). The neuron in Figure 12 is also typical in that it is inhibited by motion in a direction opposite to its preferred direction (often called the null direction). This inhibition is not found in all MT neurons, and is typically weaker than preferred direction excitation (Snowden, R. J. *et al.*, 1991; Britten, K. H. *et al.*, 1993; Qian, N. and Andersen, R. A., 1995). This push–pull kind of response is termed motion opponency and is potentially important in motion adaptation (below).

Motion direction in MT is organized in columns, like orientation in V1, and this can be seen in Figure 13. Neurons with very similar direction preferences occur together in columns, which progressively vary in their tuning from one another by a small amount or occasionally by 180° (Albright, T. D., 1984). Binocular disparity, for which MT neurons are also selective, is also organized in columns in MT (DeAngelis, G. C. and Newsome, W. T., 1999). These columns for binocular disparity appear not to be systematically arranged with respect to the direction columns, but instead form a separate, independent pattern.

MT RFs are approximately 10 times larger in diameter than those in V1, and their size scales proportionately with eccentricity. Despite this larger area, however, the directional calculations appear to occur on a small scale, much more like the dimensions of their V1 afferents. Several laboratories have measured the responses of MT neurons to apparent motion sequences as the spatial and temporal interval between the stimuli was varied (Mikami, A. *et al.*, 1986; Churchland, M. M. *et al.*, 2005). In all of these experiments, it was evident that MT cells were directional over spatial intervals much smaller than the dimensions of the RF of the MT cell, and more similar to those of V1 afferents. These observations, together with the direct observations that MT-projecting V1 cells are themselves directional (Movshon, J. A. and Newsome, W. T., 1996), strongly make the case that MT inherits its directionality from earlier structures, rather than calculating it *de novo*.

MT cells are tuned for speed as well as for direction, though the tuning is often quite broad (Maunsell, J. H. R. and Van Essen, D. C., 1983b). The speed tuning of cells in MT are either low-pass, preferring slow speeds, well tuned for intermediate speeds, or broadly tuned (Maunsell, J. H. R. and Van Essen, D. C., 1983b; Lagae, L. *et al.*, 1993).

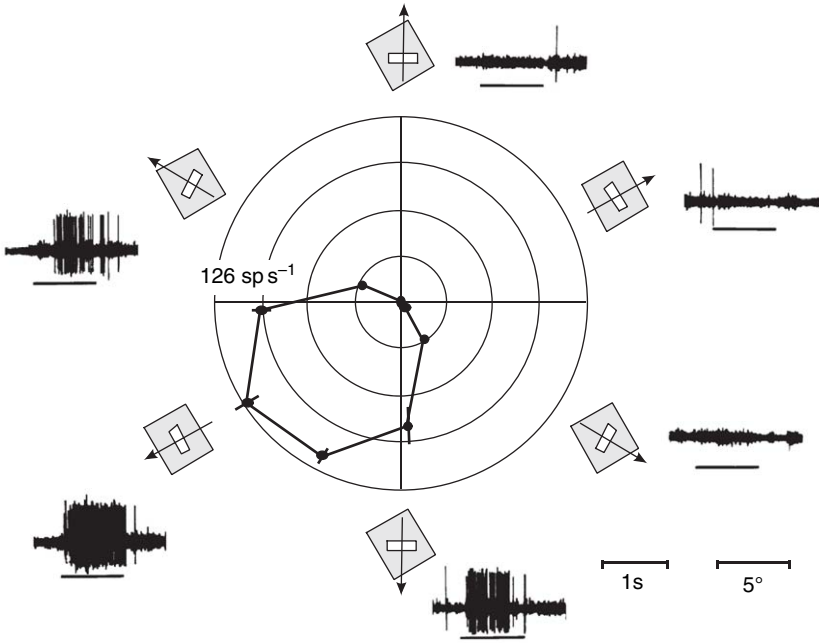

Figure 12 Tuning of a directionally selective cell in MT. Illustrated is the pattern of data typically obtained in studies of direction selectivity. The polar plot displays the magnitude of the cell's response to eight directions of motion. Also depicted are the neural spiking responses for six of the motion directions. The speed of the movement is approximately 5° s^{-1}. The neuron's preferred direction is down and to the left. From Maunsell, J. H. R. and Van Essen, D.C. 1983b. Functional properties of neurons in the middle temporal visual area (MT) of the macaque monkey: I. Selectivity for stimulus direction, speed and orientation. J. Neurophysiol. 49, 1127–1147.

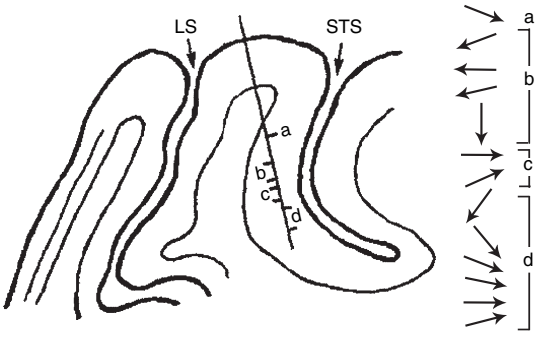

Figure 13 Oblique penetration through MT (modified from figure 3 of Dubner, R. and Zeki, S. M. 1971. Response properties and receptive fields of cells in an anatomically defined region of the superior temporal sulcus. Brain Res. 35, 528–532) showing the shifts in preferred direction indicative of the direction columns subsequently demonstrated by Albright T. D. *et al.* 1984).

There is a systematic, if not extremely precise, relationship between speed preference and RF location, with more foveal neurons preferring slower speeds, and more peripheral ones, faster speeds. In general, response latencies are decreased as speed is increased (Raiguel, S. E. *et al.*, 1999). MT firing rates appear to be correlated with speed perception (Priebe, N. J. and Lisberger, S. G., 2004; Liu, J. and Newsome, W. T., 2005). Last, the response dynamics of MT neurons, which are typically fast, also carry a covert signal of target acceleration (Lisberger, S. G. and Movshon, J. A., 1999).

2.10.3.3 Motion Integration: The Aperture Problem

The small scale of directional neurons' RFs in V1 causes each neuron to see only a small part of a moving object. The orientation selectivity of a V1 neuron additionally means that each neuron can detect only the component of velocity at right angles to the edge; the component parallel to the edge is invisible. This is frequently referred to as the aperture problem because the RF is like a small window through which the cell sees the motion in the world, as illustrated in Figure 14. To represent the actual motion of an object, these local estimates of individual object boundaries must be combined in some way. The history of this problem has been a good example of the cross-fertilization of theory, psychophysics, and physiology in neuroscience.

The problem is fairly straightforward – the retinal motion of an object is represented by a two-

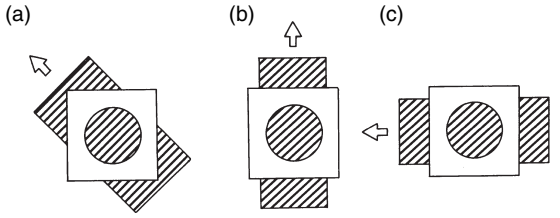

Figure 14 Because of the aperture problem, the local motion in each of the apertures is the same even though the true motion of the grating differs. Reprinted from Movshon, J. A., Adelson, E. H., Gizzi, M. S., and Newsome, W. T. 1985. The Analysis of Moving Visual Patterns. In: Study Group on Pattern Recognition Mechanisms (*eds*. C. Chagas, R. Gattass, and C. Gross), pp. 117–151. Pontifica Academia Scientiarum.

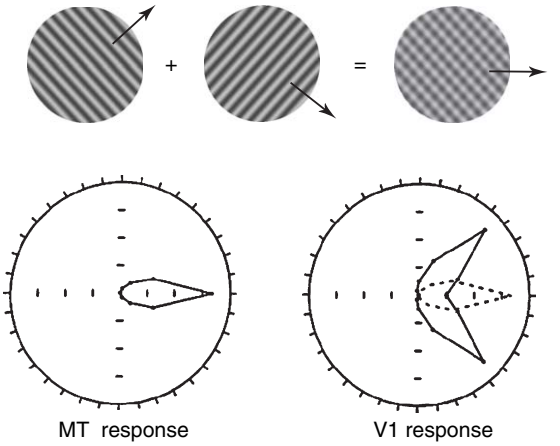

Figure 15 Responses in MT and V1 to pattern motion stimulus (the moving plaid). 20% of MT cells are selective to the plaid motion, 40% respond to component motion, and 40% are intermediate.

dimensional vector, yet each V1 (or other equally fine-grained directional neurons) can only estimate a single dimension. To estimate the actual velocity of an object with multiple contours, one must be able to integrate the different vectors corresponding to individual moving contours. Plaid stimuli make a good tool to probe this integration process, since one can superimpose multiple single vectors to study integration at either a perceptual or physiological level. Perceptually, subjects integrate the motions of each component of a plaid very well, under a variety of conditions (Levinson, E. and Sekuler, R., 1975; Adelson, E. H. and Movshon, J. A., 1983).

There are several theoretical possibilities as to exactly how the individual vectors are combined to extract the true object velocity. The veridical answer is provided by a method known as intersection of constraints, but this is a bit complex to implement physiologically (Movshon, J. A. *et al*., 1985). A weighted vector-average solution will produce a good approximation to the correct motion under most real-world situations, and perceptual experiments show that the visual system often makes the mistakes predicted by this approach, when views are brief or when reduced contrast or added noise weakens the image (Stone, L. S. *et al*., 1990; Yo, C. and Wilson, H. R., 1992). More recently, a Bayesian solution has been proposed, which is both physiologically plausible and consistent with perception in a variety of test situations (Weiss, Y., 2000).

At the physiological level, it is clear that some MT neurons integrate multiple directions of motion in such plaid stimuli, as illustrated in Figure 15. When tested with a plaid containing two different directions, such pattern direction-selective neurons respond maximally when the plaid pattern is moving in their preferred direction, but this is a stimulus in which neither component of the plaid is so moving. Another fraction of MT cells responds in a component direction-selective manner, like V1 cells, and another fraction is intermediate (Movshon, J. A. *et al*., 1985).

There is one other possible mechanism for computing the true plaid motion. Because of their small RFs, cells in V1 are unable to signal the true motion of a contour, and so V1 has generally been regarded as incapable of carrying true motion information for plaid patterns. However, a subpopulation of V1 neurons, called end-stopped cells, are capable of signaling motion independently of the contour (Pack, C. C. *et al*., 2003). These cells respond only to the endpoints of the contour, and would thus be sensitive to the true motion of the object.

While many of the accounts of how pattern motion is perceived are fairly abstract and theoretical, some have been phrased in more biological terms, directly testable by physiological experiments in area MT. An earlier model of the integration of inputs by MT neurons (Simoncelli, E. P. and Heeger, D. J., 1998) incorporated a specific pattern of projection from V1 to MT, followed by a modest nonlinearity in MT. This model provided a good account of pattern direction selectivity in MT, as well as other phenomena. More recently, an elaboration of this model has been formed and directly tested (Rust, N. C. *et al*., 2006) and, by subtle cell-to-cell changes in the pattern of connections into and within MT, could account not only for pattern direction selectivity itself, but also for the range of cell responses from component- to pattern-direction selective.

2.10.3.4 Integration for Speed Perception

It is less intuitively obvious that integration is also useful for correctly estimating the speed of moving objects. The reason is that individual features of a moving object, even if they are all moving in the same direction, have different spatial scales and thus will activate multiple populations of V1 afferents sensitive to different spatial frequencies. When an object with multiple spatial frequencies moves with a single velocity, the spatial and temporal frequencies in the object will be correlated, with a constant of proportionality capturing the speed of motion. This relationship is illustrated in Figure 16. A long-standing question is to what extent MT cells integrate their multiple inputs so as to encode a single speed. MT neurons have the opportunity to integrate in this way, since their spatial and temporal bandwidths are substantially larger than those in V1 (Movshon, J. A. *et al.*, 1988). When tested with multiple combinations of spatial and temporal frequencies, many MT cells have a slant in their joint tuning, indicating a preference for a single velocity, irrespective of the exact spatial and temporal frequency composition (Movshon, J. A. *et al.*, 1985; Perrone, J. A. and Thiele, A., 2001; Priebe, N. J. *et al.*, 2003). The extent of this slant, however, varied considerably across cells, and a substantial minority of MT cells was not evidently tuned for a single speed, consistent with broad tuning for speed. Interestingly, however, V1 complex cells are often slanted as much as MT cells (Priebe, N. J. *et al.*, 2006), so it is not clear this property is entirely formed *de novo* in MT. However, these measurements were made with single gratings, and the effects of summation in MT were more apparent when compound stimuli containing multiple spatial frequencies were used. In order to account for the measured speed selectivity of MT neurons to such stimuli, a modest summation nonlinearity is required (Priebe, N. J. *et al.*, 2003). While not modeled in exactly the same way, it is likely that this summation nonlinearity is closely related to that employed by Rust N. C. *et al.* (2006) to account for plaid direction selectivity. Thus, qualitatively similar summation is important in how MT solves two distinct, important problems requiring integration of multiple inputs. This suggestion still needs to be made explicit with a larger-scale theoretical account, however.

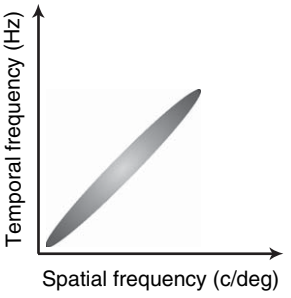

Figure 16 The spatial and temporal frequencies in a single moving object are proportional, with higher spatial frequencies being modulated at higher temporal frequencies. The slope of this relationship is the speed of the object.

2.10.3.5 The Problem with Integration: Segmentation Is Needed Too

Although integration appears vital for solving the aperture problem and might be used by the motion system for speed perception, it has a problem. It would be detrimental to our perception of the world if our visual system integrated the motions from two independent objects in the same part of the visual scene. The solution to this problem is segmentation, a mechanism that separates the signals from different objects that are to be analyzed separately.

Opposing motions from two objects in the same space usually occur on different planes of depth, otherwise they would collide. Motions that occur at different depths modulate MT responses. Many neurons in MT are tuned for depth, and responses to the preferred motion are less suppressed by nonpreferred motion when it occurs at a different depth (Qian, N. and Andersen, R. A., 1994; Bradley, D. C. *et al.*, 1995).

About half of the cells in MT, especially in the supragranular layers, are likely to possess antagonistic surrounds. A surround is a spatial region that extends well beyond the classical RF and suppresses the neuron's response when a stimulus is large enough to activate it (Lagae, L. *et al.*, 1989). These surrounds are also directional, and suppress most actively for stimuli moving in the cell's preferred direction, and least for motion in the opposite direction. The surrounds in MT cells are frequently very irregular in shape, sometimes only encompassing a small fraction of the perimeter of the RF center (Xiao, D. K. *et al.*, 1995). Surrounds in MT are clearly important in segmenting multiple motions in the image.

Many neurons in MT have antagonistic surrounds that modulate the response to a central stimulus.

A surround stimulus that moves in a direction, speed, and/or depth that differs from the central stimulus will cause the least suppression (Allman, J. M. *et al.*, 1985; Xiao, D. K. *et al.*, 1997; Bradley, D. C. and Andersen, R. A., 1998).

In contrast to these antagonistic surrounds, reinforcing surrounds, which prefer motion in the same direction as the center, have also been described (Allman, J. M. *et al.*, 1985; Tanaka, K. *et al.*, 1986). These different types of surrounds, preferring the same or opposite direction, appear to be columnarly organized in owl monkey (Born, R. T., 2000). It seems reasonable that this organization separates the important functions of wide-field and object motion processing.

Surrounds even show the ability to switch between integration and segmentation. When the motion signal is weak, say because the contrast is low, the visual system integrates to increase its sensitivity (Tadin, D. *et al.*, 2003). Under low contrast conditions, some MT neurons actually fire more to a large stimulus that includes the normally suppressive surround, as illustrated in Figure 17 (Pack, C. C. *et al.*, 2005).

Color also appears to be a useful segmentation cue in MT. Croner L. J. and Albright T. D. (1999) found that, like human observers, individual neurons in MT are better able to discriminate motion direction when the motion signal is a different color than the noise.

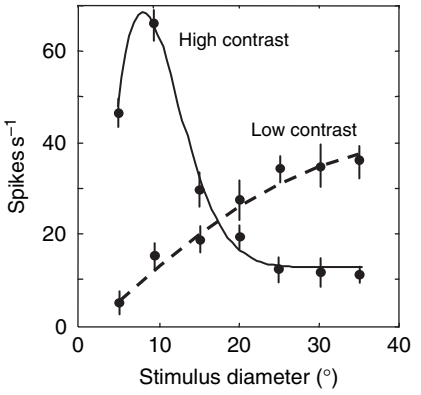

Figure 17 Center-surround interactions in MT. Effect of contrast on center-surround interactions for one MT neuron. When tested with high-contrast random dots (RMS, root-mean-square contrast 9.8 cd m^{-2}) the neuron responded optimally to a circular dot patch 10° in diameter and was strongly suppressed by larger patterns. The same test using a low-contrast dot pattern (0.7 cd/m^2) revealed strong area summation with increasing size. Reprinted from Pack, C. C., Hunter, J. N., and Born, R. T. 2005. Contrast dependence of suppressive influences in cortical area MT of alert macaque. J. Neurophysiol. 93, 1809–1815.

2.10.3.6 The Effect of Contrast

Contrast is a primary attribute of any visual stimulus, and its effects on motion perception and physiology have been extensively studied. The most conspicuous change in motion perception at low contrast is a decrease in perceived speed (Thompson, P., 1982; Thompson, P. and Stone, L. S., 1997), although this effect paradoxically reverses if the spatial frequency is high enough (Thompson, P. *et al.*, 2006). This result has guided a large number of studies exploring the effect of varying contrast at all levels of the motion system. The goal is to identify the important loci that limit the perception of speed, based on where the physiologically observed effects of contrast are most consistent with the perceptual phenomena. The problem is that one needs a good model as to how any candidate neuronal population supports the perception of speed, and as of now, the experimental results have not clearly pointed to a single model.

Neurons at all levels of the visual system give graded, monotonically increasing responses to rising contrast. M neurons have considerably steeper contrast-response functions than P neurons (Derrington, A. M. and Lennie, P., 1984). Also, neurons in MT have substantially steeper contrast-response functions than those of neurons in V1 (Sclar, G. *et al.*, 1990). Therefore, at any level of the motion system, the primary effect of reducing contrast will be to reduce firing rates, but this will be by differing amounts for different populations.

In V1, reducing contrast lowers both preferred spatial and temporal frequency (Holub, R. A. and Morton-Gibson, M., 1981; Albrecht, D. G., 1995; Carandini, M. *et al.*, 1997; Sceniak, M. P. *et al.*, 2002). At the cell's preferred temporal frequency, reducing contrast acts to decrease the neuron's preferred spatial frequency. And likewise, at the preferred spatial frequency, reduced contrast decreases the preferred temporal frequency. In addition, recent findings show that most V1 cells, regardless of their directionality, have reduced speed tuning under lowered contrast (Livingstone, M. and Conway, B. R., 2006). This effect was well correlated with differences in the space–time slant of the RF with different contrasts.

In MT, the situation is more complicated. Three laboratories have measured MT responses to either random-dot (Pack, C. C. *et al.*, 2005; Krekelberg, B. *et al.*, 2006) or grating (Priebe, N. J. *et al.*, 2003; Priebe, N. J. and Lisberger, S. G., 2004) stimuli as contrast is varied. All agree on only one finding, that overall, firing rates are lower at lower contrast. Priebe and

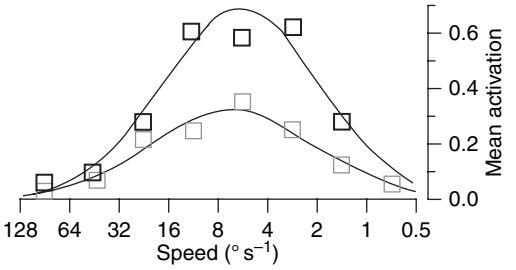

Figure 18 Population response in MT for gratings of high or low contrast. The figure summarizes the population response as a function of the preferred speeds of the neurons (x axis). Black and gray symbols and curves show the population codes for contrasts of 32% and 8%, respectively. Symbols show averages of neural responses binned according to preferred speed and curves show Gaussian fits to the symbols. Lowered contrast reduced the neural response, but did not shift the population response. Adapted from Priebe, N. J., Cassanello, C. R., and Lisberger, S. G. 2003. The neural representation of speed in macaque area MT/V5. J. Neurosci. 23, 5650–5661.

Lisberger (Priebe, N. J. *et al.*, 2003; Priebe, N. J. and Lisberger, S. G., 2004) examined both perceptual and physiological effects of changing spatial frequency and contrast. In these experiments, contrast had the expected effects of reducing perceived speed, but did not systematically change the distribution of responses in MT (Figure 18). This would appear to call into question any simple model where the distribution of activity in MT directly supports the perception of speed. However, a fairly standard vector average model of how the population codes for speed can be reconciled with these data if you add an additional feature that lowers the overall speed estimate as the population response drops. This is not very different from a Bayesian prior assumption of low speed, which was also used in the interpretation of plaids by Weiss Y. *et al.* (2002).

When random-dot stimuli are employed with varying contrast, the effects on speed tuning are more pronounced. Lowering the contrast of dots profoundly shifts speed-tuning functions to lower values. This is particularly true for neurons that prefer higher speeds in the first place (Pack, C. C. *et al.*, 2005; Krekelberg, B. *et al.*, 2006). While at first glance this might appear consistent with perception, it is actually backwards. As contrast is lowered, neurons preferring higher speeds become relatively more active, and a vector average would predict a higher speed percept. The same thing would be true for the other main class of readout models, which extract speed from a ratio between the activities of a high-speed and a low-speed subpopulation (Perrone, J. A., 2006; Thompson, P. *et al.*, 2006). While the authors reject both these simple models, they also do not attempt to employ the Bayesian idea that allowed the grating responses to be consistent with perception. Because the effects on the population are different in magnitude for the two classes of stimuli, it is not yet clear that a single model will work for both, but this has not yet been tried.

2.10.3.7 Relating MT to Perception

Area MT has become a favored target for experiments designed to quantitatively relate neuronal responses to perception. There is now a large body of work from several laboratories testing the hypothesis that MT is both necessary and sufficient for motion perception. Necessity is best established using lesion methods (Schiller, P. H. *et al.*, 1987; Newsome, W. T. and Paré, E. B., 1988), and these experiments show that MT is necessary for normal motion sensitivity, but also clearly suggest that other areas contribute as well. Even after large MT lesions, substantial perceptual abilities remain.

Sufficiency is somewhat more difficult to demonstrate, and relies on correlation between neuronal and perceptual performance. A large number of experiments of this sort have been performed, testing the relationship between neuronal spiking activity in MT and performance on a variety of tasks (Britten, K. H. *et al.*, 1992; Thiele, A. *et al.*, 1999; Dodd, J. V. *et al.*, 2001; Uka, T. and DeAngelis, G. C., 2001; Grunewald, A. *et al.*, 2002; Krug, K. *et al.*, 2004; Liu, J. and Newsome, W. T., 2005). On direction discrimination between opposed alternatives when limited by noise, the average MT cell had thresholds nearly equal to the monkeys'. When the alternatives were made closer together, MT performance dropped relative to the monkeys and only the best neurons showed performance similar to that of the monkey (Dodd, J. V. *et al.*, 2001; Purushothaman, G. and Bradley, D. C., 2005). Last, in the discrimination of small speed differences, again, only the best neurons showed performance equivalent to what the monkey could do (Liu, J. and Newsome, W. T., 2005).

Another demonstration of the correlation between MT activity and perception comes from the discovery of a trial-by-trial correlation between neuronal discharge and monkey choices, when both are measured at the same time. This kind of correlation does not suggest sufficiency, but instead suggests that the neurons might be contributing to the signals that

support performance. The first such observation (Logothetis, N. K. and Schall, J. D., 1990) was not entirely encouraging. In a study of binocular motion rivalry, MT signals were frequently associated with the percept, but this association was approximately as often in the expected direction (higher rates when the animal reported preferred direction motion) as in the opposite. More recently, such correlations have been described in the context of difficult perceptual choices, and most of these experiments reveal a preponderance of the more intuitively sensible positive correlations. This association is commonly described using a metric termed the choice probability (Britten, K. H. *et al.*, 1996). Significant choice probabilities have now been observed in MT in the context of a number of motion-related tasks, including direction discrimination (Britten, K. H. *et al.*, 1996; Purushothaman, G. and Bradley, D. C., 2005), cylinder rotation judgment (Dodd, J. V. *et al.*, 2001; Parker, A. J. *et al.*, 2002), and speed discrimination (Liu, J. and Newsome, W. T., 2005). Figure 19 illustrates choice probability for the cylinder rotation judgment.

Perhaps the most direct evidence linking MT to perception comes from electrical microstimulation experiments. While lesion experiments cannot distinguish a direct, causal role from an indirect, supporting role in perception, microstimulation can directly support a causal role in perception. Newsome's group has documented this kind of involvement in direction discrimination (Salzman, C. D. *et al.*, 1990; 1992; Salzman, C. D. and Newsome, W. T., 1994; Newsome, W. *et al.*, 1995) as well as in speed discrimination (Liu, J. and Newsome, W. T., 2005). They found that microstimulating a cluster or column of similarly tuned MT neurons biased the animal's decisions in favor of the direction of motion encoded by the stimulated neurons.

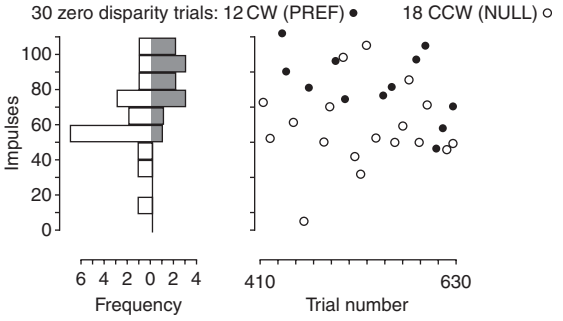

Figure 19 Trial-by-trial correlation between neuronal response and behavioral choice for a single cell in an ambiguous cylinder rotation task (zero disparity). The uppermost plots illustrate the neuronal responses for trials in which the animal chose CW (PREF) rotation or CCW (NULL) rotation. Higher firing rates (impulses) were correlated with CW (PREF) choices. The choice probability for this cell was high, 0.79, based on the separation of the distributions as can be seen in the scatterplot. The distribution of choice probabilities, bottom panel, shows a mean choice probability of 0.67, ranging from 0.35 to 0.98. Adapted from Dodd, J. V., Krug, K., Cumming, B. G., and Parker, A. J. 2001. Perceptually bistable three-dimensional figures evoke high choice probabilities in cortical area MT. J. Neurosci. 21, 4809–4821, figures 3 and 5.

Taken together, this body of evidence forms one of the strongest sets of data linking a specific cortical area to perception. It suggests, furthermore, that the same neuronal signals contribute to many aspects of motion discrimination. However, one must be careful not to over-interpret these data as well. In particular, it is tempting to suggest that MT is the only, or a single dominant player in motion perception, and nothing in this body of work supports this conclusion. Likewise, it is now clear that MT is not completely specialized for motion perception. An extensive series of studies from the laboratory of DeAngelis and colleagues has documented that MT is extensively involved in judgments of stereoscopic depth as well (DeAngelis, G. C. *et al.*, 1998; Uka, T. and DeAngelis, G. C., 2004; 2006). Therefore, it would be unwise to make too strong a claim that MT is completely specialized for motion analysis. It is also potentially revealing that the quantitative details of the relationship between neuronal activity and perception varies widely from task to task, which suggests that the readout mechanisms by which such signals inform perception are not fixed but are instead malleable and context dependent.

2.10.3.8 Adaptation

Neural adaptation is the change in neuronal responses due to preceding stimulation of the cell. Because adaptation effects are often profound at both the neural and perceptual levels, it has been widely used as a tool to probe the neuronal signals underlying perception. Motion adaptation, in particular, has a long and influential history, because of the vivid motion aftereffect (MAE), or waterfall illusion (Wohlgemuth, A., 1911; Krekelberg, B. *et al.*, 2006). One unusual aspect of this phenomenon is that, unlike many other adaptation phenomena, it results in a positive percept – motion is visible where none is present on the retina. This has led to a large literature reporting both positive (facilitatory) and negative neuronal effects at all levels of the motion system. While detailed examination of this complex and often contradictory literature is beyond the scope of

this chapter, one can safely say that there is no clear consensus yet as to the critical neuronal changes underlying the MAE.

Perceptually, the MAE can be extremely local, suggesting a critical locus early in the motion system, and there is good supporting evidence from both cat and monkey physiology experiments (Verstraten, F. A. *et al.*, 1999; Freeman, T. C. *et al.*, 2003; Blaser, E. *et al.*, 2005) of directionally selective adaptation effects as early as V1. However, there is clear evidence from perceptual experiments of specific adaptation to complex (global) motion patterns as well (Regan, D. and Beverly, K., 1978; Snowden, R. J. and Milne, A. B., 1997), which presumably points to additional changes late in the motion system. These have not been explored in physiology experiments, and this clearly is an important future direction.

Perhaps the most compelling physiology experiments come from work in MT. In experiments using only two directions of motion (preferred and antipreferred), substantial decrements in activity following preferred direction motion adaptation have been observed (Petersen, S. E. *et al.*, 1985; Van Wezel, R. J. and Britten, K. H., 2002), consistent with the biases seen in motion perception. In a recent study, adaptation reduced the activity of neurons with tuning similar to the adapting stimulus, narrowed the tuning curve, and importantly, shifted the tuning of cells with nearby preferred directions toward the adapted direction (Kohn, A. and Movshon, J. A., 2004). These attractive shifts in tuning and narrowed bandwidths resulted in nearby directions of motion eliciting a greater difference in neural response and therefore an effect that was perceptually repulsive. Thus, the neuronal results appear consistent with the perceptual effects, and probably arise from local inhibitory interactions between neurons tuned to different directions in MT or prior structures.

In a related set of experiments using different speeds, rather than different directions, Van Wezel R. J. and colleagues (Krekelberg, B. *et al.*, 2006), found that adaptation to a particular speed reduces the firing rate for neurons tuned for nearby speeds while narrowing their tuning curves. This is again consistent with the perceptual effects of adaptation on speed identification and discrimination. So, overall, a fairly good case is developing that MT is one important locus supporting adaptation at the perceptual level, but again, these preceding experiments do not allow one to conclude that MT is the critical locus, and more work is needed at other locations in the motion system.

2.10.3.9 Attention and Memory

Visual perception depends not only on retinal information, but also on cognitive or top-down information. Such cognitive contributions to vision include directed attention for selecting behaviorally relevant stimuli in visual scenes as well as remembered associations of visual stimuli. Neuroscientists have long sought correlates of such high-level, cognitive phenomena, and the motion system of cortex is a good example of the success of this endeavor.

One form of directed attention operates as a kind of spotlight, to spatially select the most important locations in the visual scene for processing (Treisman, A. M. and Gelade, G., 1980). Another, related form of attention is directed toward particular visual features (e.g., a particular color or motion direction) irrespective of where they appear in space. This form of attention may be useful in the integration of low-level attributes for the perception of coherent objects (Treisman, A. M. and Gelade, G., 1980; Wolfe, J. M. and Bennett, S. C., 1997). Many studies have shown that attention can be directed to a spatial location independent of the eye fixation location (Posner, M. I., 1980; Desimone, R. *et al.*, 1985).

The seminal observation of attention-related effects in MT comes from Treue S. and Maunsell J. H. (1999). In this experiment, a monkey was instructed to attend to one of two independently moving dots and respond to a small speed change; responses to speed changes of the other stimulus were not rewarded. This caused substantial modulation, so that the firing rate was much higher (~80%) when the attended dot was moving in the preferred direction than if the unattended dot was doing so. The two situations were designed to be retinally identical, and only the attentional state of the animal caused the modulation. In this experiment, both spatial- and feature-based attention might contribute, since the dots were in different locations and also were moving in different directions.

Recent experiments allow us to dissociate the magnitude of purely spatial- and feature-based attention effects in MT. Purely spatial attention effects were measured in the experiments of Seidemann E. and Newsome W. T. (1999), in which a monkey was cued to attend to one of two patches of dots, one of which was within the RF. When the directions of the two were the same, spatial attention alone would modulate responses, and when it was directed within the RF of the cell, modulation of about 9% was observed. Conversely, Treue and colleagues have measured the

modulatory effects of attending to different directions, while keeping spatial attention fixed, and found slightly larger effects of 12–20% (Treue, S. and Martínez Trujillo, J. C., 1999; Martinez-Trujillo, J. C. and Treue, S., 2004). In these experiments, the attended stimulus was often as far as 20° from the RF under study, suggesting that feature-based attentional modulation can cross large distances in cortex.

Subsequent work has further expanded our understanding of the phenomenology of attentional modulation. The modulation by either spatial- or feature-based attention appears to be dominantly a multiplicative change in response magnitude (a gain change; Motter, B. C., 1993; McAdams, C. J. and Maunsell, J. H., 1999). The finding (Womelsdorf, T. *et al.*, 2006) that spatial attention can actually shift the RF of MT neurons toward the attended location while shrinking the RF around it, is consistent with the spotlight view of spatial attention. However, these shifts were modest in magnitude, relative to the diameter of the RF.

Quantitative comparison of the magnitude of attentional modulation in MT in a related task (Cook, E. P. and Maunsell, J. H., 2002b) indicated that the magnitudes of the neuronal changes in MT were insufficient to explain the simultaneously measured behavioral performance benefits. Interestingly, directional neurons in area VIP had the opposite problem – attentional modulations larger than those seen behaviorally. This also helps to reinforce the view that signals supporting performance on such discrimination or detection tasks are pooled from multiple cortical areas.

These experiments (and others not mentioned here) certainly help to constrain the mechanisms underlying attentional modulation, but do not directly lead to a circuit-level hypothesis as to how the changes take place, or where the attentional control signals arise. These are challenges for the next generation of attention experiments.

Neurons in MT also carry information about the remembered direction for a memory delay task. Pasternak and colleagues recorded the activity of MT neurons during the delay in a motion discrimination memory task (Bisley, J. W. *et al.*, 2004). They found that many neurons fired during the delay period, especially near the end before the test stimulus would appear. Furthermore, the neurons' firing rates differed with respect to the motion direction of the remembered stimulus. Again, this is strong evidence for the presence of signals concerning the cognitive context being present in the firing rates of MT neurons. It would be parsimonious to suggest that these might be a consequence of the same top-down signals responsible for directed attention, but this has not been directly tested.

2.10.3.10 Human MT

Human MT was one of the first areas identified using functional magnetic resonance imaging (fMRI) techniques, which noninvasively image the blood flow changes in the human brain that are consequent to local neuronal activity. While low in spatial and temporal resolution, the method allows one to ask questions regarding human brain function that cannot be addressed in animal experiments.

Human MT is usually localized using fMRI by repeatedly presenting a coherently moving dot stimulus followed by a motionless dot stimulus to the subject. The activity resulting from the stationary stimuli is subtracted from the trials containing the moving stimuli, leaving behind only the motion-induced activity, as can be seen in Figure 20 (Deutsch, C. K. *et al.*, 2000).

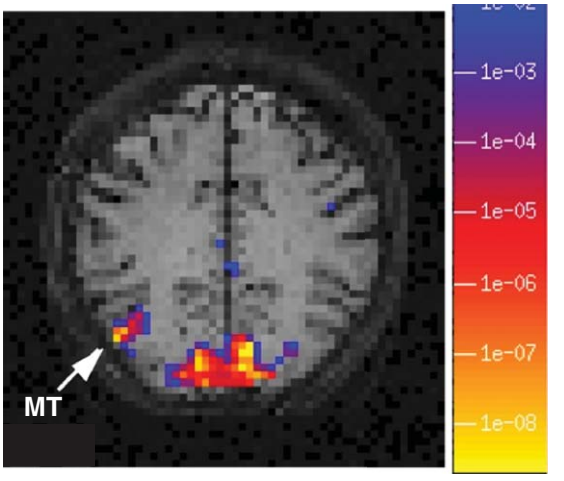

Figure 20 Functional magnetic resonance imaging (fMRI) image showing relative levels of activation in both MT and V1 while the subject was looking at dot motion. Patches of activation are defined as activity to the moving dots minus activity to static dots. The flame scale to the right shows the amount of functional activation. The most common imaging technique, blood oxygen level-dependent fMRI, measures change in local deoxyhemoglobin to indirectly measure neuronal activity. Reprinted from Deutsch, C. K., Oross, S., DiFiore, A., and McIlvane, W. J. 2000. Measuring brain activity correlates of behavior: a methodological overview. Exp. Anal. Hum. Behav. Bull. 36–42.

Since many motion responsive areas are localized in this task, putative MT in humans is often called hMT to highlight the difference. hMT or the MT complex in humans probably includes some of the areas near MT in monkeys, such as MST. It is likely that these motion areas in humans are the evolutionary homologs of those found in monkeys, but this idea is still unproven because of the difficulty of doing the necessary anatomical and physiological experiments in human subjects.

Still, much has been learned about human MT that supports its similarity to macaque MT. The area is retinotopically organized and responds best to motion-based stimuli. Much like the firing rate of MT cells in macaque, the degree of MT activation in humans depends on the coherence of the motion signal and is contrast sensitive, both important features of area MT (Tootell, R. B. *et al.*, 1995; Rees, G. *et al.*, 2000). In addition, Smith and colleagues (Smith, A. T. *et al.*, 1998) have shown that human MT is strongly activated by both first- and second-order motion. Human MT is also speed gradient sensitive (Martinez-Trujillo, J. C. *et al.*, 2005).

These studies have been vital to indicating the strong functional homology between human and macaque MT. In contrast with these similarities, it seems as though humans have more motion sensitive regions than the macaque, including area V3A and parts of the intraparietal sulcus (Orban, G. A. *et al.*, 2003). In addition, the relationship between the blood oxygen level-dependent fMRI population response and single-neuron physiology is becoming clearer (Rees, G. *et al.*, 2000).

Finally, hMT has been shown to activate vigorously even in the absence of visual motion (Culham, J. C. *et al.*, 1999; Kourtzi, Z. and Kanwisher, N., 2000). Studies measuring hMT activation as a result of the mental imagery of rotation support its role in motion perception, and the idea that mental imagery engages similar neural networks as direct perception (Cohen, M. S. *et al.*, 1996).

2.10.4 Global Motion

When we move through the world, a large-scale pattern of image motion results. This motion was called optic flow by J. J. Gibson (1950), and moving organisms use it for navigation and visual guidance of trajectory. The problems of how optic flow appears on the retina, how this pattern is processed in the brain, and how our trajectory is perceived have been the focus of considerable effort. The field shows the benefits of the interaction between theory, perceptual studies, and physiological approaches.

2.10.4.1 What Is Optic Flow?

The terminology used in the literature can be confusing, since optic flow, retinal flow, global motion, and wide-field motion are all used, with sometimes overlapping and sometimes distinct meanings. However, the patterns of motion themselves are fairly straightforward, with helpful regularities. Any observer trajectory produces a physical pattern of movement vectors simply from geometrical optics, and this is what Gibson originally termed optic flow. The projection of this pattern on the retina is technically referred to as retinal flow, which incorporates the independent movements of the eye. However, the use of the term optic flow for this retinal pattern is now widespread, and we will adopt it as well. For normal forward motion, the pattern of motion that results contains expansion across the frontal field of vision. The direction of the movement, or the destination, is a point at the center of the expansion. Gibson termed this point the focus of expansion, and theorized that it is used by the visual system to determine the heading, or path along which observer movement occurs. The exact pattern of motion surrounding this focus of expansion is also influenced by the depth structure of the scene: distant points result in lower speeds and nearby points result in high speeds, though both velocity vectors radiate directly from the focus of expansion. Where depth discontinuities happen at the edges of occluding objects, there are abrupt changes in the velocity on either side of the boundary (Figure 21).

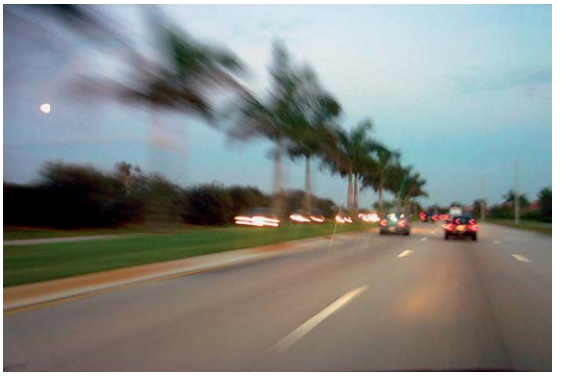

Figure 21 Example of expanding optic flow pattern, possibly seen while driving.

The pattern of motion is also affected by anything that causes the angle of gaze to shift over time. Most commonly, this would be head or eye movements causing rotations of the gaze direction even as one's trajectory remains on a straight line. This will superimpose an additional vector pattern on the pattern produced by the motion, which complicates the image considerably. If one is tracking an object in the scene – a common occurrence – the focus of expansion will no longer be at our direction of heading, but will instead be centered on the object we are tracking. If, however, we are tracking some independently moving object, there will often be no focus of expansion at all, so any method that simply tracks the focus of expansion will fail.

Perceptual experiments on optic flow have been closely guided by the foregoing theoretical considerations, but the history of physiological experiments on cortical mechanisms have been more guided by a reductionist desire to break down complex motion patterns into simple ones that can be parametrically varied for neuronal tuning measurements, making direct comparison difficult at times. In this account, we will focus on the physiology, while attempting to relate these results to the underlying theory whenever possible.

2.10.4.2 Area Medial Superior Temporal

Many cortical areas respond to optic flow, including the ventral intraparietal area (VIP), superior temporal polysensory area, area 7A and MT. However, the first area in which optic flow signals were discovered in monkey cortex, the medial superior temporal area (MST), has received by far the most attention. Area MST adjoins MT on the cortical surface and receives dense feed-forward input from MT (Boussaoud, D. *et al.*, 1990; 1992). Like MT, it is recognizable in histological sections as a densely myelinated region. MST can be further divided into two subregions, which differ in their connectivity and in their response properties. The distal subdivision of the MST (MSTd) tends to respond better to very large stimuli, while neurons in the lateral subdivision, MSTl, often show poor responses to such stimuli and better responses to small stimuli (Tanaka, K. *et al.*, 1986). This distinction is quantitative, however, and neurons in both places show many common properties, including large RFs and a preponderance of directionally selective responses. RFs in MST are many times larger than those in MT; some of them cover the entire visual field. Unlike in MT, there appears to be no relationship between RF size in MSTd and eccentricity (Orban, G. A., 1997). MSTd RFs cover a broad range of sizes, usually very large, at all eccentricities. These RFs also tend to be more elliptical than MT and often extend into the ipsilateral visual field (Duffy, C. J. and Wurtz, R. H., 1991).

The visual responses of MST neurons (most studies have focused on MSTd) are more complex than those of earlier levels of the motion system. Most MST neurons are selective for direction, and generally prefer faster speeds than does MT (Tanaka, K. and Saito, H., 1989). But what is most distinctive about MST is the selectivity for nonuniform motion patterns. A substantial fraction of MST neurons are selective for complex motion patterns, such as expansions, contractions or rotations (Saito, H. *et al.*, 1986; Duffy, C. J. and Wurtz, R. H., 1991; Graziano, M. S. A. *et al.*, 1994). Most MST cells, however, have a mixture of selectivities, including both for simple translation as well as for some combination of selectivity for rotation or radial motion (Duffy, C. J. and Wurtz, R. H., 1991). The latter can be well characterized using a spiral space, which represents different combinations of radial and rotary motion (spirals) as an angle in two-dimensional space. This is shown in Figure 22(a), which illustrates a single MST neuron responding to a family of such stimuli. It is clear that the cell is not tuned to a cardinal axis (pure rotation or contraction), but to a spiral stimulus that is a mixture of contraction and clockwise rotation, as in Figure 22(b), When one examines the population of neurons in MST, all possible directions are tiled by these responses, but there is a clear overabundance of expansion-selective neurons (Graziano, M. S. A. *et al.*, 1994). This has been viewed as good evidence for a role of MST in the analysis of optic flow during self-motion, since motion is usually forward, and expansion will thus be more common in natural viewing than contraction. Additional evidence supporting such a role for expansion-preferring cells in MST is that their responses are usually tuned for a particular location of the focus of expansion (Duffy, C. J. and Wurtz, R. H., 1995).

However, it is possible that even neurons not specifically tuned for expansion might have a role in the analysis of self-motion. Several models of heading perception (Lappe, M. and Rauschecker, J. P., 1993; Ben Hamed, S. *et al.*, 2003) rely on signals that are sigmoidally tuned for different headings. To examine this physiologically, researchers have turned to a more natural class of stimuli that simulate linear translations in particular directions in three-dimensional space,

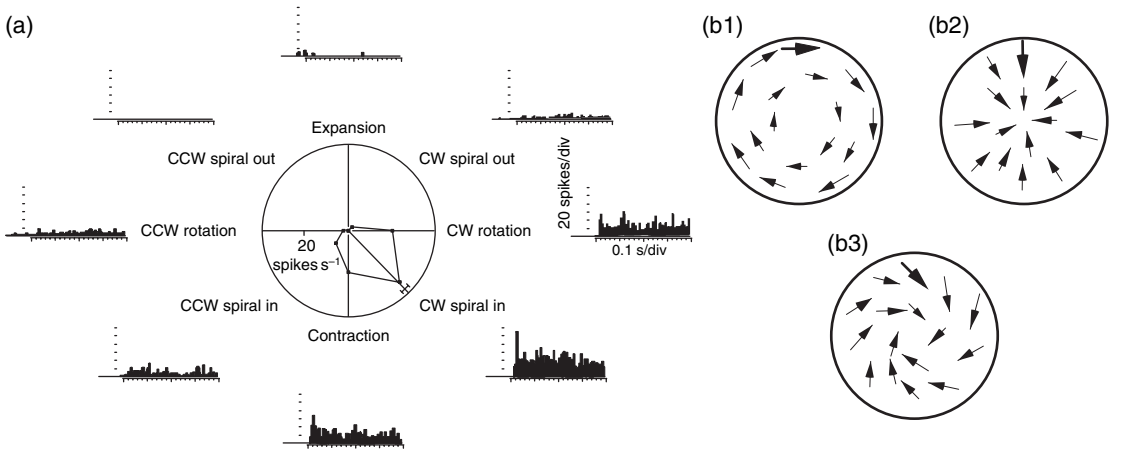

Figure 22 (a) The complex motion tuning of an example MST cell. This cell is tuned to clockwise contracting spiral. The radius represents the response magnitude. In the perimeter are the response histograms, summed over 10 trials. The dashed line marks the onset of the visual stimulus. CW, clockwise; CCW, counterclockwise. (b) Schematic drawings of spiral space random dot stimuli, for rotation (1), contraction (2), and spiral (3). Reprinted from Graziano, M. S. A., Andersen, R. A., and Snowden, R. J. 1994. Tuning of MST neurons to spiral motions. J. Neurosci. 14, 54–67.

usually through a random cloud of points. Such a stimulus is shown in Figures 23(a) and 23(b). Using such a stimulus, one can directly examine the tuning of neurons for heading, irrespective of the exact visual components of the pattern to which the cell is responding and observe tuning functions such as that shown in Figure 23(c). This neuron is clearly very informative about small changes of heading direction, especially near directly ahead where its firing rate changes most rapidly. This is also the region of heading directions to which observers are most accurate in estimation of their heading.

2.10.4.3 Extraretinal Inputs

In addition to its well-characterized motion responses, MST is the first area on the motion system to conspicuously represent nonvisual attributes. These include the position and velocity of the eyes (Sakata, H. *et al.*, 1983; Squatrito, S. and Maioli, M. G., 1997), as well as vestibular signals (Gu, Y. *et al.*, 2006). It is clear that MST is intimately involved in the generation of pursuit eye movements, since lesions to MST have deleterious effects on pursuit (Dursteler, M. R. *et al.*, 1987) and since microstimulation of MST can transiently interfere with ongoing pursuit. There are two classes of functional interpretation to the mixture of such extraretinal signals with visual motion signals. First, motion is the dominant signal supporting smooth pursuit, so having explicit motor signals mixed in with sensory signals might play a role in feedback correction of pursuit. Second, and not exclusively, ongoing eye movements distort and bias the optic flow signals upon which heading perception is based, so having direct access to such extraretinal signals might allow the neural representation of heading to be stable in the face of such interference.

Evidence for this latter view comes from experiments measuring MST heading tuning in the presence of eye and head movements (Bradley, D. C. *et al.*, 1996; Page, W. K. and Duffy, C. J., 1999; Shenoy, K. V. *et al.*, 1999; Britten, K. H. and Van Wezel, R. J., 2002). In such experiments, it has been found that MST neurons can partially or completely compensate for ongoing eye and head movements, producing a fairly stable representation of heading. One example of such stability is shown in Figure 23(c). This shows tuning with the eyes stationary, as well as in the presence of smooth pursuit to an independent target moving at $10^\circ\,s^{-1}$. Such pursuit might be expected to shift the focus of expansion by up to 60° in space, yet clearly the tuning functions of this cell are nearly unaffected by the pursuit. This suggests that MST can compensate quite well for ongoing eye movements, though the mechanism by which eye movement signals and visual signals are combined remains an open question.

MST also contains neurons that fire during pursuit or when the target temporarily disappears, while

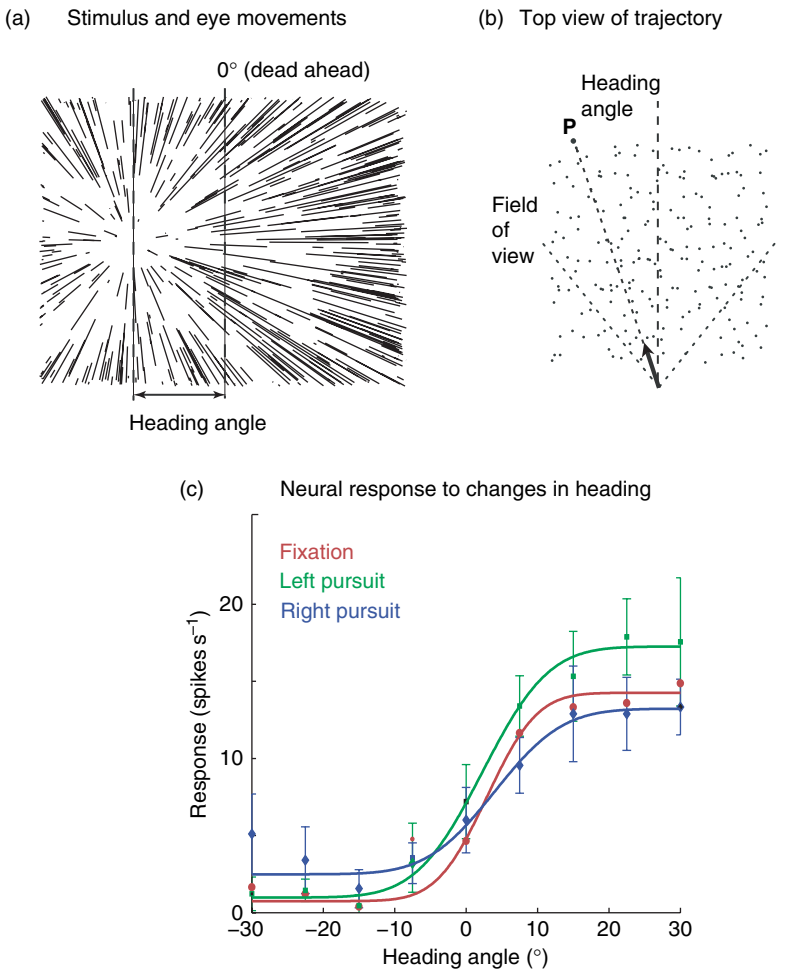

Figure 23 (a) The simulated geometry of the virtual trajectory of the animal with respect to the stimulus, as seen from above. The arrows are approximately to scale and illustrate large heading angles. Note that the cloud of points contains simulated depth. (b) Appearance of left and right heading stimuli, as seen from the observer's perspective. The length of each line shows the speed of each dot, which is inversely proportional to its simulated depth. The vertical dashed line corresponds to a heading of zero, directly ahead of the subject. The heading corresponds to the center of radial expansion, in the absence of eye movements. (c) Sigmoid function of neuronal response to changes in heading angle. This cell prefers rightward heading and shows increased firing rate to more rightward heading angles. This cell also shows excellent response stability in the presence of pursuit eye movements.

others only fire for moving stimuli in the absence of eye movements (Komatsu, H. and Wurtz, R., 1988; Newsome, W. *et al.*, 1988; Komatsu, H. and Wurtz, R., 1989; Erickson, R. G. and Their, P., 1991). In combination, these cells would be capable of differentiating between real motion in the world and motion that results from self-movement. These pursuit neurons could aid in optic flow processing by signaling the speed of the eye movement (Lappe, M., 1998; Ben Hamed, S. *et al.*, 2003). Direct measurements of population responses in MST, however, find that by whatever mechanism, the focus of expansion tuning is maintained in the presence of eye movements (Page, W. K. and Duffy, C. J., 1999).

Another source of relevant extraretinal inputs arises from the vestibular system. These are useful in locomotion because the vestibular system is capable of providing additional information about both linear and angular acceleration, which might help to augment heading signals or help to compensate for head rotations. In the dark, many MST neurons respond robustly to both circular and linear accelerations (Page, W. K. and Duffy, C. J., 1999; Gu, Y. *et al.*, 2006). Several things are interesting about these

signals. First, the tuning of where maximal response occurs under visual and vestibular stimulation is often very divergent. Second, when visual and vestibular inputs are combined, the responses do not appear to reflect a linear sum of these inputs, but instead a visual dominance. This is most evident when the precision of heading signals is compared under visual stimulation alone and combined visual/vestibular stimulation (Gu, Y. *et al.*, 2006). The use of such inputs to visual cortex in the guidance of locomotion is an exciting new area of research, and much remains to be understood about it.

2.10.4.4 Relating Media Superior Temporal Area to Perception

The presence of such optic flow signals suggests a role for MST in the perception of movement or of self-motion from optic flow. Several stronger lines of evidence support this suggestion more directly. MST is clearly involved with simple direction discrimination, from the experiments of Celebrini S. and Newsome W. T. (1995). The entire suite of observations that allowed the Newsome group to conclude that MT was directly involved in a direction discrimination task were replicated nearly identically in MST, showing that MST has at least as strong a role in simple direction discrimination as does MT. It is worth emphasizing that this task involved the discrimination of pattern motion on a scale of 10–40° in size, clearly not global in a strict sense. Therefore, it is clear that MST contributes essential information to medium-scale motion perception as well, and is not specialized for truly global motion.

In a related series of experiments, Heuer H. W. and Britten K. H. (2004) simultaneously recorded neuronal and behavioral responses to spiral space stimuli, to be able to ask how well MST supported performance on such discriminations. Interestingly, the results of this study supported a weaker relationship between MST activity and behavior on this class of discriminations. Neuronal sensitivity was on average much lower than was behavioral sensitivity, and choice probabilities were weak or nonexistent. Clearly, MST is not specialized for complex pattern motion over translational motion, and if anything is more involved in simpler motion judgments.

Consistent with this view, and with the idea that translational motion is a useful indicator of horizontal heading direction, Britten K. H. and Van Wezel R. J. (2002) microstimulated MST while an animal performed a heading discrimination task. Microstimulation of columns of MST cells biased the animal's response toward the heading direction preferentially encoded by the stimulated cells. Interestingly, the results were both larger and more systematic when the animal was engaged in pursuit eye movements. The results support a role for MST in the perception of self-motion from optic flow and the determination of heading during eye movements. Furthermore, since the sites stimulated in these experiments were not tuned for expansion, but instead for optic flow with a horizontal component, it supports the use of simpler motion components in discriminating heading, as suggested by recent population-based models (Lappe, M. and Rauschecker, J. P., 1993; Ben Hamed, S. *et al.*, 2003).

2.10.4.5 Other Areas with Optic Flow Responses

Area MST is not the only structure to respond to optic flow signals. Area 7A, in the parietal lobe, receives input from MST and VIP and also responds to optic flow patterns (Read, H. L. and Siegel, R. M., 1997; Siegel, R. M. and Read, H. L., 1997). In addition to being tuned for directions of optic flow, some cells in area 7A respond selectively to a class of optic flow stimuli, such as all radial motion (expansion and contraction). Also, optic flow responses in 7A are modulated by the position of the eyes (Read, H. L. and Siegel, R. M., 1997).

Area VIP, in the ventral intraparietal sulcus, receives feed-forward connections from MT and in turn projects to area 7A. Like MST and area 7A, many cells in VIP are tuned for optic flow patterns, most preferring expansion over contraction (72%; Bremmer, F. *et al.*, 2000; 2002). Furthermore, individual cell's response magnitudes are modulated by the location of the focus of expansion; thus, the population is capable of encoding the animal's heading. VIP also contains a large number of directionally selective neurons, and neuronal activity has been documented to be correlated with both choice and reaction time in a motion-onset-detection task (Cook, E. P. and Maunsell, J. H., 2002a).

Though VIP has many similarities with MST, with both encoding the direction of heading, there are differences that specify each area's particular role in optic flow processing. For VIP, the area's neurons respond to visual, vestibular, and tactile stimuli; MST lacks these somatosensory inputs. This has led to the suggestion that VIP may have the important function of encoding object movement in

near-extrapersonal space (Duhamel, J. R. *et al.*, 1998; Cooke, D. F. and Graziano, M. S., 2003; Graziano, M. S. and Cooke, D. F., 2006). If this suggestion is correct, as seems likely, then it is probable that VIP signals are used on both near-field and far-field tasks, and is not completely specialized for any single task.

Many areas contain a subset of neurons that have a significant response to optic flow stimuli, including motor cortex, area 5, and area PEc in the dorsal pathway and area STPa in the ventral pathway. In the motor cortex, neurons respond selectively to one type of optic flow stimuli (Merchant, H. *et al.*, 2001). In area PEc, in the dorsal portion of the superior parietal lobe, cells are responsive to optic flow and are selective for the location of the focus of expansion with respect to the fovea (Raffi, M. *et al.*, 2002). This selectivity could encode the heading direction of the animal.

Finally, area STPa, the anterior part of the superior temporal polysensory area, receives input from motion processing stream areas MST and 7A and from object processing area TEO. Neurons in this area show a selectivity for object motion, with most cells only responding to movements of objects in the world, rather than optic flow caused by self-motion (Hietanen, J. K. and Perrett, D. I., 1996a; 1996b). In addition, the area has direction preferences biased toward expansion with upward and downward motion stimuli. Since STPa responds best to the motion of external objects and prefers radial expansion, this suggests an involvement in the processing of looming stimuli.

2.10.4.6 Higher Motion Areas in Cat Visual Cortex

In the cat visual system, there are many cortical areas involved in processing motion. Compared with the monkey, the cat visual system appears much simpler, containing fewer extrastriate areas (Payne, B. R., 1993). The posteromedial lateral suprasylvian (PMLS) region has a preponderance of direction selective cells and is strongly reciprocally interconnected with area 18, a V2 homolog. Cells in these areas are also speed tuned (Price, N. S. *et al.*, 2006). As discussed earlier in this chapter, the directional responses in both these areas might very well arise from the input of lagged and nonlagged X and Y cells (Saul, A. B. and Humphrey, A. L., 1990; Mastronarde, D. N. *et al.*, 1991).

The cat homolog for motion processing area MT is the lateral suprasylvian visual area (LS; Zeki, S., 1974), and the two have very similar connectivity, retinotopy, and direction-selective responses. Area LS, like MT, has RFs with very large silent surrounds that have a preferred direction opposite that of the RF center. These surrounds are inhibitory for motion in the same direction as the center. Possibly, these cells are used to differentiate between the cat shifting its gaze, where image motion is uniform and activates the surround, and its locomotion, which would cause an optic flow field with many different directions.

When Sherk H. *et al.* (1997) compared LS cells' responses under these two different kinds of image motion, they found many cells responded better to the optic flow, most showing very little suppression, and 20% responded better to the optic flow than to RF center stimulation. However, LS is quite heterogeneous, with cells that prefer large-field frontoparallel motion, optic flow with a strong bias for expansion, or small moving bars (Kim, J. N. *et al.*, 1997). Surprisingly, during large field optic flow movies, the preferred direction of the cell was modified. Many cells responded robustly to the optic flow stimulus even though the direction of motion in the RF was orthogonal to the cell's preference (Mulligan, K. *et al.*, 1997; Sherk, H. *et al.*, 1997).

It is probably significant that one-fifth of cells in LS are selective for disparity, and many are selective for motion in depth (Toyama, K. and Kozasa, T., 1982; Toyama, K. *et al.*, 1986). Furthermore, bilateral lesions of area LS results in permanent deficits in direction discrimination and the perception of structure from motion (Rudolph, K. K. and Pasternak, T., 1996), demonstrating that LS plays a role in integrating motion signals.

The exact homolog of area MST in the cat remains unknown, and thus optic flow processing appears distributed. To begin with, area 18 contains a subset of cells selective for motion in depth (Cynader, M. and Regan, D., 1978). These neurons might be useful during locomotion, though this is dubious since most of these preferred motion away from the animal. There is another population of neurons in area 18, with large RFs showing directional selectivity for large fields of moving dots. Many of these RFs are in the lower visual field and respond best to downward motion, consistent with the visual stimulation during locomotion. Also, as in the monkey, these cells are part of a network that projects to the cerebellum, which is involved in the ongoing guidance of motor activity.

2.10.5 Conclusion

The motion system in visual cortex has been a very fruitful target of study over the years, as the work on this chapter has attempted to show. It has been studied from a variety of perspectives, and clearly much has been learned. However, almost equally striking is how much remains to be learned. One of the most obvious lacks is perhaps central to the entire system: we do not yet know the circuit on which directional selectivity in cortex is based. While good models exist, and even a good sketch of V1 circuitry up to the loci where directional cells appear, the synaptic basis of directionality remains shrouded in mystery.

Similar ignorance of local circuits becomes even more salient as one moves away from V1; we have a much better grip on the phenomenology than we do on the mechanisms. For instance, while we can say with certainty that MT cells integrate across space, spatial frequency, and temporal frequency, we do not know whether this happens monosynaptically from afferent connections, indirectly through multiple feed-forward pathways, or even laterally from other MT cells. As in the case of the V1 circuit questions, the difficulty of critical experiments should not forbid the attempt. It is possible that with the improvement of high-resolution *in vivo* imaging methodologies, such questions will become more tractable in the near future.

Large-scale questions also remain about the relation between structure and function in the motion system. While this pathway, and particularly area MT, has been a fertile proving ground for experiments that relate the firing of cortical neurons quantitatively to perception, there are suggestions that this work is far from complete. Specifically, this line of investigation has clearly suggested that the perception of motion is a widely shared function. Nonetheless, most experiments have looked at single areas. We also have little idea how the perceptual readout of these many areas works, or how the multiple signals are combined in the service of awareness or visually guided behavior. This is a set of questions that existing techniques will probably be very adequate to address.

Oddly, there also seems to be a dearth of theory in the analysis of cortical motion mechanisms, despite the extensive theory associated with motion perception. In part, this is related to a lack of data to support more biologically realistic, structural models of motion processing, and in part it probably stems from theorists' desires to develop more elegant mathematical models. But in any case, the field clearly appears to be at a stage where more crosstalk between theory and experimental test would be of direct and immediate benefit.

As this brief and incomplete list shows, there is at least no worry that the book on cortical motion is now closed, and it is exciting to think that the next 20 years might provide as many important insights as has the last two decades.

Glossary

adaptation Neural process by which the response to a constant stimulus decreases over time.

aperture problem Ambiguity of the true velocity of 1D features (such as lines or edges) sampled through spatially delimited windows. See Section 2.11.4.

barber pole A visual stimulus consisting of a 1D grating moving behind a rectangular aperture. Though the predominant motion energy is in the direction perpendicular to the grating's stripes, the perceived direction of motion is parallel to the long axis of the aperture. This motion illusion was one of the first demonstrations that terminators are powerful motion cues. See Section 2.11.19 and Figure 9(a).

Bayesian model A class of models that use Bayes' theorem for inverting conditional probabilities to incorporate prior knowledge of the world into the intrepretation of sensory data. In a typical Bayesian model of some visual function, one wishes to calculate the probability of occurrence of a particular visual stimulus, *S*, based on some

evidence variable, E, such as a measurement derived from a noisy image or a noisy neural response (written as $p[S/E]$, or the probability of S given E). Typically one has a measure of the inverse probability ($p[E/S]$, the probability of measurement E given stimulus S) and makes use of the prior likelihood of that particular stimulus ($p[S]$) to produce a better estimate, called the posterior probability, of the stimulus that produced the evidence.

bistable Ambiguous visual stimuli that may be seen in either of two mutually exclusive configurations; common non-motion examples are the Necker cube or face-vase illusion.

center-surround opponency: A receptive property in which the neuron's response to a preferred stimulus decreases as the size of the stimulus increases.

coherence/transparency Two mutually exclusive possible perceptual experiences when viewing a moving plaid pattern. Coherence refers to the situation in which the pattern appears to move as a single rigid entity; transparency, to the situation in which the two component gratings appear to slide over one another independently, creating the impression that the nearer surface is partially transparent.

component/pattern prediction Two possible predictions of a neuron's direction tuning curve in response to a 2D plaid stimulus, based on its tuning curve to a 1D grating stimulus; see Sections 2.11.14 and Figure 4.

correspondence problem Problem in determining, for two images that are separated in space and/or time, which image elements belong to the same features. See Section 2.11.2 and Figure 1.

cross-correlation Mathematical technique for determining the degree to which two images are similar; of the two images are snapshots in time, cross-correlation can be used to detect motion; see also correspondence problem; see Section 2.11.6 and Figures 1 and 2.

differentiation Mathematical operation for calculating the rate of change of one variable, x, with respect to another variable, y. The result of the operation is referred to as the **derivative** of x with respect to y. If x represents the position of an object and y is time, differentiation yields the velocity of the object.

end-stopping Receptive property in which responses to extended contours are suppressed by inhibitory zones lying outside the central activating region along the axis of the cell's preferred orientation; see Section 2.11.22 and Figure 10.

extrastriate Regions of visual cortex beyond primary visual cortex (V1).

feature tracking Strategy for solving the aperture problem by locating corresponding 2D features, such as corners of objects or the intersections of plaids, in successive image frames and then calculating their direction of motion; see Section 2.11.19; See also, selectionist model.

frequency domain Shorthand for spatiotemporal frequency domain, a coordinate system for specifying visual motion in terms of two dimensions of spatial frequency (the frequency of a sinusoidal modulation of image intensity of each dimension of 2D space) and one of temporal frequency (the modulation of image intensity over time); the frequency domain representation can be related to the more familiar coordinates of x, y, and t by taking the Fourier transform of the space–time coordinates. Any visual motion sequence (i.e., a movie) can be decomposed into a series of pure sinusoidal gratings (ω_x, ω_y, and ω_t) of differing amplitudes and phases in the same way that complex sounds can be broken down into sums of pure tones (a pure tone being the auditory equivalent of a sinusoidal grating). Because any local sample from a rigidly moving object is constrained to lie on a plane in the spatiotemporal frequency domain, this coordinate system has been used to characterize the receptive fields of neurons that solve the aperture problem. See Figure 6; see also F-plane model.

F-plane model Short for Fourier-plane model. Refers to a class of computational models in which pattern selectivity is created by summing the responses of neurons whose spatiotemporal frequency receptive fields all lie on a single plane in spatiotemporal frequency space; the F-plane model actually represents the power spectrum of the space–time image, as it discards the phase component. See Section 2.11.16 and Figure 6. See also frequency domain.

hypercomplex Term used by Hubel D. H. and Wiesel T. N. (1965) to refer to the receptive fields of neurons that did not respond to extended contours; see also end-stopping and Figure 10.

hypersurface A technical term from differential geometry used to generalize the notion of a curve into multiple dimensions; in the present context it is used to describe the set of points that define the

image intensity as a function of two spatial dimensions (x, y) and one temporal dimension (t).

integrationist model A class of computational model of motion integration that integrates all 1D motion signals to determine the 2D direction of motion; see Section 2.11.15.

intersection of constraints (IOC) Method for computing 2D motion by combining measurements from two or more 1D samples; see Section 2.11.16 and Figure 6.

layers (of cortex) Cut in cross section, the cerebral is a laminar structure, typically consisting of six layers visible with histological stains for cell bodies (such as Nissl stain); neurons whose cell bodies occupy different layers have different patterns of inputs and outputs.

masking Phenomenon in which one visual stimulus impairs the ability to detect another visual stimulus.

motion after-effect (MAE) Visual illusion in which prolonged adaptation to motion in one direction causes a subsequently viewed stationary scene to appear to contain motion in the opposite direction.

motion opponency A receptive field property in which null direction motion causes a reduction in the neuron's response.

MT The middle temporal visual area; also known as V5.

multistable Ambiguous visual stimuli that can be seen in one of several (more than two) mutually exclusive configurations.

nonlinear Any mathematical operation, such as squaring, for which the operation on the sum of two or more inputs is not the same as the sum of the operation's results on the individual inputs; that is, for a linear operation, f, it must be true that $f(a+b) = f(a) + f(b)$. If this relationship does not hold, the operation is nonlinear.

nonlinear systems identification A method for deriving a model of a system based on the relationship between input and output. Often applied to the study of receptive field structure; See Section 2.11.6 and Figure 2.

normalization In the present context it refers to the operation of dividing the output of a given visual filter by the sum of the outputs of all such filters.

plaid Visual motion stimulus created by superimposing two drifting sinusoidal gratings. See Section 2.11.13 and Figure 4.

plaid test Method of classifying visual neurons by comparing responses to both 1D gratings and 2D plaids. See Section 2.11.14 and Figure 4.

preferred/null direction Direction of motion that produces the best/worst response of a given neuron

receptive field The region of visual space in which visual stimuli can alter the firing rate of a neuron; the definition also includes other features of the visual stimulus required, such as the direction of motion, or the temporal pattern of inputs.

retinal disparity Difference in the relative positions produced by a single image on the retinas of the two eyes; such disparity can be used to determine the relative depth (distance from the fixation plane) of the object.

Riemann tensor Mathematical operation used to measure the curvature of a hypersurface.

segmentation The process of determining which image elements belong together.

selectionist model A class of computational model of motion integration that first filters out motion signals emanating from 1D features and thus selectively combines motion signals arising from 2D features; see Section 2.11.25.

sinusoidal grating A visual stimulus in which the intensity of the image is modulated by a sine function along one dimension; if I is a 2D image with the horizontal dimension indexed by x and the vertical dimension by y, the function $I = \sin(\omega x)$ would produce a vertically oriented sinusoidal grating of spatial frequency ω.

T-junction An image feature in the configuration of the letter T generally produced by a near surface occluding a far one.

type I plaid A visual plaid stimulus whose component gratings have directions that lie on opposite sides of the IOC resultant; see Figures 7(a) and 7(b). See also plaid.

type II plaid visual plaid stimuli whose component gratings have directions that lie on the same side of the IOC resultant; See Figure 7(c). See also plaid.

vector sum/average Method for combining two 2D velocity vectors, which have both a direction and a magnitude (speed), to obtain a single velocity vector; geometrically this is done by placing the tail of one vector to the head of the other and drawing a line from the tail of the first to the head of the second, yielding the sum; to obtain the average, the magnitude of the vector sum is scaled by dividing its length by the sum of the lengths of the two

individual vectors. Both methods yield a velocity vector having the same direction. See Figure 7.

V1 Primary visual cortex, the first stage of visual processing in the cerebral cortex and the first stage at which direction selectivity appears; also known as area 17 and striate cortex.

winner-take-all Mathematical operation which, given two or more inputs, produces an output equal to the strongest input, ignoring the weaker ones.

2.11.1 Introduction – Visual Motion

At the level of the retina, visual motion occurs whenever something in the environment moves, or whenever the observer moves or rotates his or her eye. Thus visual motion is a fundamental aspect of our interactions with the world around us. Because retinal image motion has multiple possible causes, it is both computationally challenging and richly informative, serving many functions besides the detection of moving objects. The pattern of image motion created by self-motion, for example, can be used to recover depth and to detect object boundaries as well as to aid in orienting to the environment. It is also useful in guiding eye movements that serve to stabilize images on the retina for high-acuity form vision. However, because movement is a feature that distinguishes many items of great behavioral relevance – potential predators, prey, and mates – the detection of object motion is particularly important.

The latter function will be the focus of this review. In particular, we will address the difficult problem of how information from elementary motion detectors is combined in order to provide accurate representations of the motion of objects. To consider the mechanisms by which brains achieve this integration, we will draw from two sources of data: (1) psychophysical experiments, mainly from humans, and (2) microelectrode recordings from neurons in early cortical motion processing regions of the monkey (and other mammals) – particularly the primary visual cortex (V1) and the middle temporal area (MT). The data will lead us to a discussion of general theoretical approaches as well as specific computational models of motion integration.

2.11.2 The Correspondence Problem

To see why motion integration is necessary, it is first helpful to consider some general problems associated with the basic, low-level detection of motion. Figure 1 shows a pair of successive snapshots of a scene containing the motion of a rigid object. Superimposed on the second panel is the motion that was measured at each point by simply finding pixels in the second image whose luminance corresponded closely to nearby luminances in the first image. There are of course more sophisticated ways to measure motion, and some of them will be discussed in subsequent sections. Although it is apparent that the figure in the pair of images moved from right to left, many of the motion vectors point in other directions. The confusion stems from the fact that many of the pixels in each image have the same luminance, and there is no obvious way to match the individual pixels in the first frame to those in the second frame. This problem is often called the correspondence problem (Ullman, S., 1979), and it renders the computation of velocity difficult for both biological and artificial visual systems.

One might propose that the correspondence problem could be solved both easily and efficiently if one used fewer pixels. That is, if each pixel were the size of the moving figure, then one could imagine a motion algorithm that simply matched the mean luminance of the figure in the first frame to that of the figure in the second frame. The problem with this type of solution is that it requires a visual system that has rather low acuity, which in turn runs the risk of combining motions from separate objects into one measurement. Thus the necessity for high-acuity vision tends to complicate the measurement of quantities that require correspondence between two or more images. Stereo vision and motion are the best-studied examples of such computations. For simplicity we will initially ignore the problem of multiple moving objects and return to this difficulty in later sections.

2.11.3 Motion Noise

Figure 1 also contains a number of motion vectors (purple arrows) that do not correspond to any

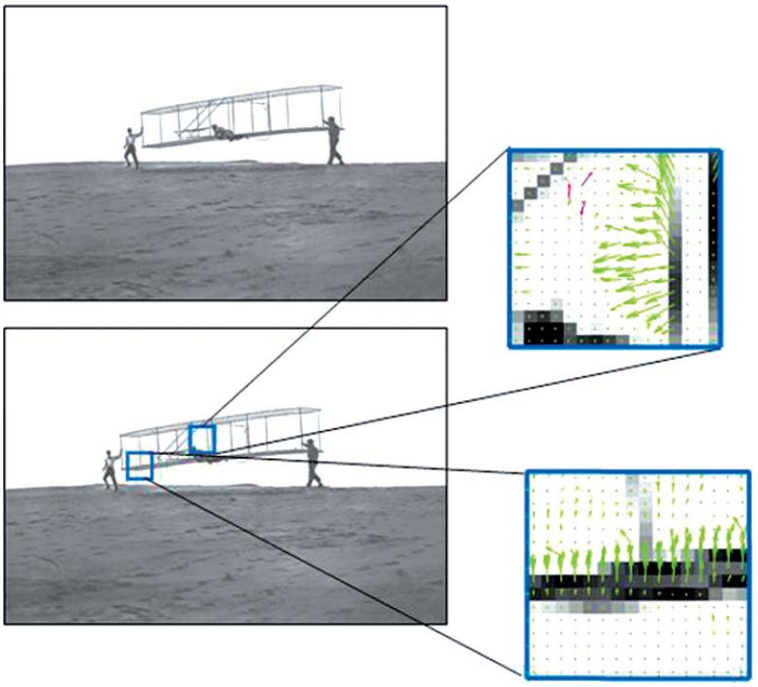

Figure 1 Orville Wright being launched by Dan Tate and his brother Wilbur, in an attempt to fly the Wright Glider in 1902. The green arrows show the average motion vector found between frame 1 (top) and frame 2 (bottom) in a small region of space around each pixel. Purple arrows indicate motion vectors that do not appear to result from the motion of the Glider, which turned out to be unfit for flight. Adapted from a public-domain image on www.first-to-fly.com.

particular object in the scene. These are false matches, in which the luminance of a pixel in the second frame happened to correspond to the luminance of a nearby pixel in the first frame. Such false matches are inevitable when dealing with inputs that are corrupted by noise, jitter, or local image correlations. The visual system possesses at least two mechanisms for reducing such noise in natural images: directional opponency and local pooling. The former has been characterized in early visual areas (Snowden, R. J. *et al.*, 1991; Qian, N. and Andersen, R. A., 1994) and is manifested as a suppression of the response to nearby stimuli moving in opposite directions. Since many sources of motion noise have equal motion energy in all directions, subtracting opposite directions of motion is an efficient way to reduce their contribution. Another way to reduce noise is to pool local measurements over some region of the visual field to produce something like an average of the different local motion vectors (Lisberger, S. G. and Ferrera, V. P., 1997; Recanzone, G. H. *et al.*, 1997; Britten, K. H. and Heuer, H. W., 1999) In fact, direction opponency is a special case of highly localized vector averaging, since the average of two vectors of equal magnitude and opposite direction is zero. It is clear that the visual system possesses mechanisms for pooling across both visual space and velocity space, and these mechanisms pose interesting problems for models of motion integration.

2.11.4 The Aperture Problem

A special case of the correspondence problem occurs when the stimulus contains extended edges or contours, as is almost always the case in natural viewing. As can be seen in Figure 1, when the stimulus consists locally of a single moving edge, the correspondence problem leads to a series of measurements indicating motion vectors perpendicular to the edge's orientation. This is a straightforward consequence of the fact that the parallel component of the actual velocity contains no time-varying information. As a result incorrect measurements will occur whenever an edge that is more than one pixel in length moves in a direction that is not perpendicular to the orientation of the edge. More generally, any motion detector will make similar errors when measuring the motion of a contour that extends beyond its field of view. Consequently, this

problem is often referred to as the aperture problem (Marr, D., 1982), as the limited field of view constitutes a kind of aperture. As it turns out, neurons in the early stages of the primate visual cortex have extremely limited fields of view, so the aperture problem is an important issue in understanding biological vision.

2.11.5 Measurement of Motion in the Primate Brain

The primate visual cortex is an example of a system that has both very high acuity and excellent sensitivity to motion. Both of these properties can be observed at the level of individual neurons. Each neuron in the early stages of the primate visual system responds to stimulation over a very small part of the visual field. In visual neurophysiology, this limited field of view is called the receptive field (RF), and most V1 RFs are smaller than the width of one's thumbnail held at arm's length. It is useful to think of RFs as pinholes (or apertures) through which neurons view the outside world. Their job is to measure certain aspects of the visual world that occur within the pinhole, and they are largely oblivious to events that occur outside this small region. Within any part of the visual cortex, neurons are found whose RFs collectively tile the whole of visual space. In addition to having a spatially delimited RF, each neuron has a limited range of visual stimuli to which it will respond. Some neurons are tuned to the shape of the stimulus, some to the color, and others are tuned to the motion that occurs within their RF. Here we focus on neurons that are selectively responsive to motion, predominantly those in V1 and MT.

2.11.6 Receptive Fields for Measuring Motion

Any system that measures motion must be sensitive to the parts of the visual image that change position over time. That is, any two separate measurements of the position of a moving object will reveal that it has changed position by a certain amount (Δx and Δy) during the interval (Δt) between the two measurements. If the measurements are accurate, these quantities (Δx, Δy, Δt) describe the velocity of the object. Such a measurement is sometimes called a second-order calculation, because it requires a conjunction of two snapshots, separated in space and time.

Second-order measurements are, both intuitively and mathematically (Poggio, T. and Reichardt, W., 1973), the minimal way to compute motion, since a single snapshot cannot meaningfully be said to contain motion. Over the last few decades, researchers have accumulated a great deal of evidence suggesting that this minimal model is actually sufficient to account for the responses of motion-sensitive neurons (Reichardt, W., 1961; Emerson, R. C. *et al.*, 1987; Emerson, R. C. *et al.*, 1992) and certain aspects of human motion perception (Adelson, E. H. and Bergen, J. R., 1985). Such second-order models are equivalent to the better-known motion-energy and Reichardt models (Adelson, E. H. and Bergen, J. R., 1985; Courellis, S. H. and Marmarelis, V. Z., 1992).

A variety of methods have been used to characterize the second-order behavior of V1 neurons, including recently an engineering technique known as nonlinear systems identification (Wiener, N., 1958). The technique is outlined in Figure 2, which shows a sequence of stimuli that were displayed on a computer monitor, which was viewed by an alert macaque monkey. The stimulus was simply a pair of spots, one black and one white, which changed position at random on each refresh of the monitor. The first frame shows the position of the spots at one point in this sequence, and the second frame shows that, a moment later, they changed position, in this case both moving to the right. The dotted squares show the positions occupied by the spots on the previous frame, and the arrows indicate the displacements of the spots from the first to the second frame.

There are four such displacements, corresponding to the four possible ways to match the spots on the first and second frames (white-to-white, white-to-black, black-to-white, black-to-black). Below these two frames is shown the cross-correlation of frame one and frame two. The cross-correlation is a simple statistical way of showing the motion energy that occurs between the frames (van Santen, J. P. and Sperling, G., 1985; Courellis, S. H. and Marmarelis, V. Z., 1992). It shows the amount of motion that occurred at a fixed temporal interval (Δt) in a plane defined by the coordinates (Δx, Δy). In other words, it shows all of the motion vectors that can be found in the two-frame sequence.

The spiking activity of a hypothetical V1 neuron that is sensitive to these motion vectors (e.g., direction-selective) is displayed above the stimulus sequence. To determine which motion vectors the neuron prefers, we average all of the cross-correlations that preceded the spike by a reasonable neuronal latency τ. This procedure allows us to

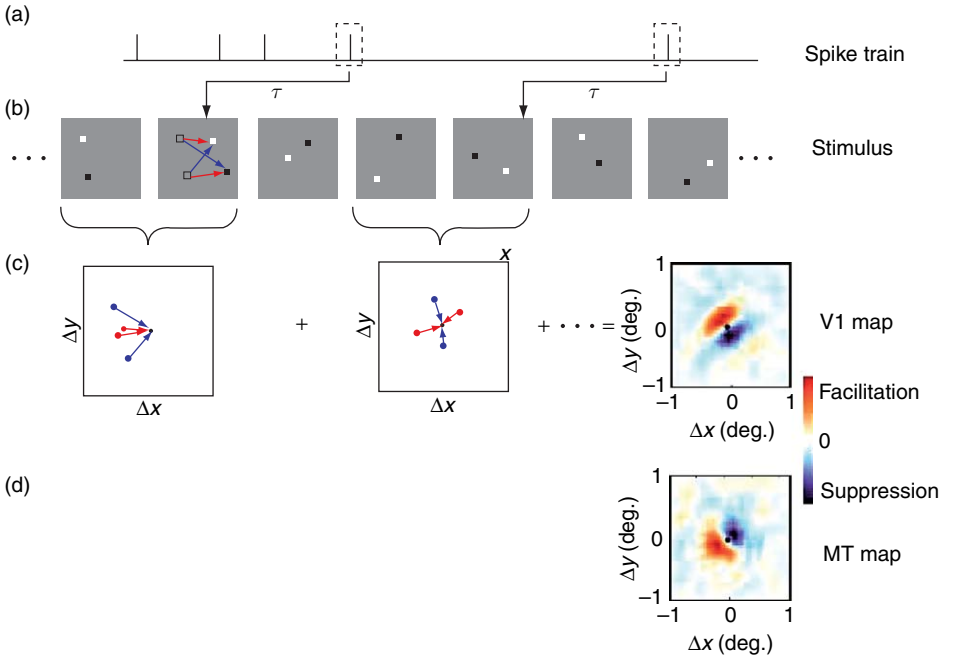

Figure 2 Reverse correlation method. (a) A hypothetical spike train produced by a neuron in response to the mapping stimulus shown in (b). Each time a spike occurs we look back in time by an amount (τ) that corresponds to the latency of the neuron. The stimulus in (b) is a pair of spots that change position randomly on each monitor refresh. Between any two stimulus frames, there are four motion signals, which can be computed by cross-correlating the two images. (c) Displacement maps, corresponding to cross-correlations between pairs of frames, with the origin corresponding to instances in which a spot appeared in the same position twice in a row. The spike-triggered cross-correlations are summed together to produce a map of the average motion vector that led to a spike. A map for an actual V1 cell is shown in the right-most column of (c). (d) A map obtained in the same way for an middle temporal (MT) cell.

characterize the selectivity of the neuron for the velocity parameters Δx, Δy, and Δt.

Such a picture for a V1 neuron is shown on the right side of Figure 2(c). The image shows the response of the neuron as a function of different values of Δx, Δy at a fixed Δt equal to 16 ms, with a neuronal latency of $\tau = 58$ ms. The neuron's response was facilitated for motion sequences down and to the right (bright orange), and suppressed for motion signals up and to the left (dark blue). We will refer such a map as a subunit to indicate that it captures a portion of the neuron's response properties, in this case the second-order selectivity for motion.

2.11.7 A Note on Terminology

The fact that the motion in a stimulus is a second-order property of the input has led to some confusion in the literature. It is common, particularly in theoretical papers, to refer to direction-selective V1 neurons as being linear. Taken literally this would be a contradiction in terms, and it is generally meant as a kind of shorthand to indicate that the neuron's RF acts as a linear spatial filter that works in parallel with a nonlinear mechanism for generating direction selectivity. Some of these models will be discussed below.

Beyond the nonlinear mechanisms that determine direction selectivity, it is generally acknowledged that additional nonlinearities are necessary to account for the behavior of visual neurons. That is, any linear combination of the output of a group of direction-selective neurons will not lead to correct estimates of stimulus velocity. We will discuss the evidence for the possible nonlinearities used by the visual cortex in some detail.

Finally, the use of the term second-order to describe the behavior of direction-selective neurons refers to the statistical order of the computation, and should not be confused with the psychophysical phenomenon called second-order motion, which is a separate concept that will not be discussed in this review.

2.11.8 The Middle Temporal Area of the Visual Cortex

MT has been the subject of intense study since it was first discovered in 1971 (Dubner, R. and Zeki, S. M., 1971). MT neurons receive most of their input from the primary visual cortex (V1), but unlike V1 neurons, they are almost without exception selective for motion direction. Neurons in the MT are also on average more tuned to retinal disparity than V1 neurons, but less tuned to stimulus shape, color, and texture (Born, R. T. and Bradley, D. C., 2005).

Perhaps the most obvious physiological difference between V1 and MT neurons is the RF size. Although the retinotopic arrangement of RFs is similar in the two areas, MT RFs are roughly 10 times the diameter of V1 RFs at any given retinal eccentricity (Albright, T. D. and Desimone, R., 1987). Thus, one might expect that MT neurons could respond to a much larger range of spatial displacements (Δx, Δy) than V1 neurons at a comparable eccentricity. In fact, previous work, using larger stimuli and long display times, has shown that MT neurons do respond better to high speeds than V1 neurons (Mikami, A. *et al.*, 1986; Churchland, M. M. *et al.*, 2005).

Stimuli identical to those used in V1 have been used to compute motion subunits for a large number of MT neurons (Livingstone, M. S. *et al.*, 2001; Pack, C. C. *et al.*, 2003a; Pack, C. C. *et al.*, 2006). An example MT subunit is shown in Figure 2(d). This neuron's response was facilitated for motion sequences up and to the right (bright orange), and suppressed for motion signals down and to the left (blue). However, other than suggesting a different preferred motion direction, the structure of this map is identical to that shown for the V1 neuron in Figure 2(c). That is, the MT neuron responds to roughly the same range of spatial displacements as the V1 neuron.

A systematic study of the subunits in V1 and MT found that the result shown in Figure 2(d) holds for every MT neuron tested: The spatial range over which the MT subunits measure motion is the same as in V1, despite the difference in RF sizes and velocity preferences between the two areas. On average, the optimal spatial displacement in MT is about 0.25°, roughly one-fiftieth the size of the RFs. Nearly identical spatial scales are found in V1 (Pack, C. C. *et al.*, 2003a; Churchland, M. M. *et al.*, 2005; Pack, C. C. *et al.*, 2006), suggesting that the MT subunits represent inputs from V1.

2.11.9 Tiling: The Simplest Model

Given these observations on the MT subunits, a simple model for motion integration by an MT neuron is a tiling model, in which large MT RFs simply sum the outputs of spatially distributed V1 neurons sharing a common preferred direction, with no interactions among the subunits. This model is supported by experiments in which the subunits are mapped at multiple points in an MT RF (Figure 3). The subunits are nearly identical at each point, a finding that held true for all the neurons examined in this way (Pack, C. C. *et al.*, 2006).

Although this is the simplest possible model for how MT RFs may be wired up, the behavior of such a neuron may, in fact, be quite complex. It depends to a large extent on how smart the inputs from V1 are. This will be an important theme that recurs throughout the ensuing discussion: How many of the seemingly more sophisticated motion processing properties of MT neurons are simply inherited from the V1 inputs?

There is a long history in visual electrophysiology of higher-order RF properties first being discovered in an extrastriate visual area, only to be re-discovered in V1 upon closer inspection. There are at least two good reasons why this occurs. First, as we have already seen for MT, extrastriate RFs tend to be much larger than those in V1, and this makes tests with more complex stimuli practically easier to conduct. For example, the miniature eye movements present during fixation are of a similar size to V1 RFs, and this makes many measurements, such as the nonlinear systems identification techniques described above, much more

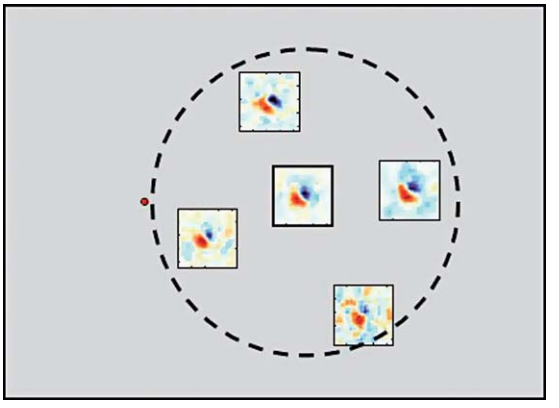

Figure 3 The result of performing the mapping procedure shown in Figure 2 at multiple points within an MT receptive field. The dot shows the fixation point, and the dashed circle shows the estimated extent of the receptive field.

technically challenging. Second, V1 is an incredibly heterogeneous visual area, containing, in essence, all of the basic visual information that it subsequently distributes to a multitude of more specialized extrastriate areas. This means that the neurons that form the principal driving input to a given extrastriate area might constitute only a tiny, and highly homogeneous, fraction of the neurons in V1, thus making comparisons of average properties between V1 and any extrastriate area difficult at best. This is clearly the case for MT, whose V1 inputs are very different from V1 as a whole: they originate mainly from a single sublayer (4B, with a small minority also coming from the so-called solitary cells of Meynert found at the border between layers 5 and 6; Maunsell, J. H. and van Essen, D. C., 1983; Shipp, S. and Zeki, S., 1989), are highly direction selective, respond over a wide range of temporal and spatial frequencies, and are very sensitive to stimulus contrast (Movshon, J. A. and Newsome, W. T., 1996). However, because they constitute such a small fraction of the total V1 population, it has been difficult to characterize very many of them in precise detail and thus to know the true nature of MT's inputs.

Given the above considerations, one way to proceed would be to start with the conceptually simple tiling model and ask what it can explain, and, perhaps more interestingly, what it might explain given certain properties of V1 neurons that have been widely documented and which are quite likely to be properties of the V1 neurons projecting to MT.

2.11.10 Tiling and Motion Noise

As noted above, one benefit of summation across many subunits within a larger RF (i.e., spatial pooling) is an improved signal-to-noise ratio. MT neurons are indeed remarkably good at detecting weak motion signals embedded in noise. In some cases the sensitivity of single MT neurons exceeds the perceptual sensitivity of the animal measured simultaneously (Newsome, W. T. *et al.*, 1989; Britten, K. H. *et al.*, 1992). In order to account for ability of MT neurons to pool many V1 inputs fully, one probably would have to add some kind of divisive normalization (Heuer, H. W. and Britten, K. H., 2002), which appears common to most cortical circuitry (Carandini, M. *et al.*, 1997), in order to compensate for the limited dynamic range of neural spiking. This can also account for the observation that when two small targets move in different directions within a single MT RF (in the absence of attentional influences) the neural response represents the average of the two motion vectors (Lisberger, S. G. and Ferrera, V. P., 1997; Recanzone, G. H. *et al.*, 1997). More on this idea below.

With respect to noise reduction, there appears to be a subtractive interaction between subunits tuned to opposite directions of motion; however, it is also possible that opponent processing is inherited from V1. Andersen and colleagues examined directional interactions in both V1 and MT using two superimposed fields of random dots moving in opposite directions (Snowden, R. J. *et al.*, 1991; Qian, N. and Andersen, R. A., 1994) . In one important study, they compared the amount of suppression produced by the null-direction dot field under conditions in which the two dot fields contained paired dots (i.e., for every dot moving in the preferred direction, there was an immediately adjacent dot moving in the null direction) versus two random dot fields that were spatially unpaired. They found, on average, more suppression to paired dot fields in MT than in V1 and concluded that it was likely that MT performed additional subunit subtraction for purposes of noise reduction (Qian, N. and Andersen, R. A., 1994). However, although the population averages were different, some V1 neurons were as suppressed by paired opponent motion as those in MT (compare figures 4 and 14 of Qian, N. and Andersen, R. A., 1994). Furthermore, the V1 cells most strongly suppressed by paired null motion were also the most strongly direction-selective (see figure 15 of Qian, N. and Andersen, R. A., 1994), a hallmark of the V1 neurons known to project to MT (Movshon, J. A. and Newsome, W. T., 1996). It is thus quite possible that the directional opponency seen in MT neurons is passively inherited from the highly specialized subset of V1 neurons that serve as its inputs. Indeed, it would seem to make sense to perform this very local comparison at a stage where RFs are small. Insofar as this is the case, the tiling model may be sufficient to account for most of the exceptional noise immunity of MT neurons. A certain degree of motion opponency is implicit in the subunits, as seen in the negative response to null-direction motion (Figures 2(c) and 2(d)). However, many models posit an additional opponency stage that subtracts the outputs of individual subunits preferring opposite motion directions (Courellis, S. H. and Marmarelis, V. Z., 1992).

2.11.11 A Problem for the Tiling Model

The tiling model simply sums the outputs of V1 neurons that share a common subunit structure, which in turn predicts the motion vectors to which the neurons will be responsive, and, as we have seen, provides improved motion integration under noisy conditions. The aperture problem, however, guarantees that many of these motion vectors will not just be randomly incorrect, but rather systematically biased (Figure 1(b)). In this case, simply adding them up will not yield the correct stimulus velocity. Rather, the visual system needs to process the motion signals in such a way as to overcome the limitations imposed by the errors that are implicit in the input. This issue lies at the heart of our remaining discussion of motion integration.

2.11.12 Conceptual Approaches to Solving the Aperture Problem

In its most basic form, the problem consists of recovering a two-dimensional (2D) velocity based on measurements that have been rendered one-dimensional (1D) by the existence of edges in the visual world and the small RFs of neurons in the brain. This necessitates some comparison of two or more motion measurements made at edges having different orientations. General approaches to the solution can be divided into two categories that differ primarily according to the stage at which the comparison occurs. In the first category of models, which includes what has become the standard model (Heeger, D. J. *et al*., 1996; Simoncelli, E. P. and Heeger, D. J., 1998), the first stage, assigned to V1 neurons, is relatively unintelligent: it nonselectively extracts only 1D motion signals which are then combined nonlinearly, at the second stage, assigned to MT, that recovers 2D velocity. Because these models combine all local 1D signals to compute the final velocity, we refer them as integrationist models.

In contrast, a second category of models places the comparison between orientations in V1, by way of known mechanisms such as end-stopping that suppress 1D motion signals in favor of motion signals emanating from 2D features. These features are just regions of the image where multiple orientations can be found locally. The second stage then simply averages the stage-one outputs to compute the final 2D velocity, an operation that can be accounted for by the tiling concept. Because the essential strategy of these models is to first select regions of the image where 2D motion measurements are most reliable and then to combine only these in the final computation, we refer to them as selectionist models.

The two categories of models are not mutually exclusive, and in many cases they make similar predictions. In the following paragraphs, we will review the psychophysical and physiological evidence supporting these different approaches, and then consider in more detail some of the computational models that have been put forth to embody them.

2.11.13 Plaids

The initial evidence for the two-stage, integrationist models came from psychophysical and physiological experiments using visual plaids (Adelson, E. H. and Movshon, J. A., 1982; Movshon, J. A. *et al*., 1985). Visual plaids are usually constructed by superimposing two, circularly windowed, sinusoidal (1D) gratings that are rotated with respect to each other (Figure 4). When the gratings are of similar spatial frequency and contrast, the resulting percept is generally of motion in a single direction, a condition referred to as coherence, with the resulting direction being the pattern (2D) direction, as distinguished

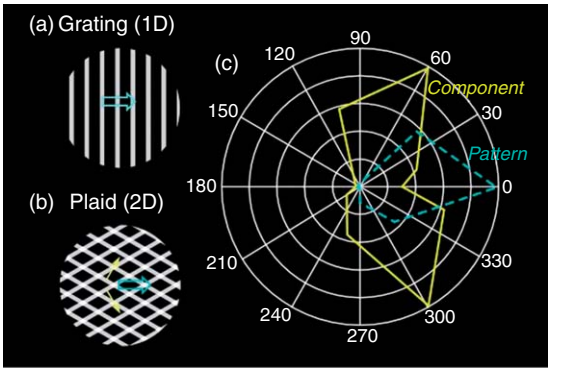

Figure 4 Plaid test for single neurons. The neuron's direction tuning curve to a one-dimensional (1D) grating stimulus (a) is used to make two predictions for the tuning curve to a two-dimensional (2D) plaid (b) in which the two components are rotated ±60° with respect to the original grating. Two predictions for an MT neuron are shown in (c) and consist of the pattern prediction (dashed curve), which is identical to that obtained with the 1D grating, and the component prediction (solid curve), which is obtained by summing two copies of the grating tuning curve that have been rotated ±60°.

from the different component (1D) directions of the two gratings comprising the plaid.[1]

In a series of psychophysical experiments, Movshon and colleagues tested the effects of masking (Adelson, E. H. and Movshon, J. A., 1982) and adaptation (Movshon, J. A. *et al.*, 1985) on human observers' tendencies to perceive coherent motion in plaids. Given the evidence that neurons in striate cortex responded optimally to contours of a particular orientation (Hubel, D. H. and Wiesel, T. N., 1962), they set out to find perceptual evidence for an orientation-selective 1D stage prior to the stage at which coherence was computed. In one experiment, they used 1D dynamic noise (oriented, flickering bars of various widths) to mask the plaids. They reasoned that, if the first-stage filtering was in fact orientation-selective, then the mask should interfere with the perception of coherence when it was parallel to one of the component gratings. In contrast, if the first stage was not orientation-selective, but rather a kind of blob-tracking mechanism that signaled the direction of the plaid's intersections, the effect of the mask would either not depend on its orientation or perhaps would be greatest when it was perpendicular to the direction of pattern motion. They found that the 1D masks were only effective when oriented within 20° of one of the component gratings, in agreement with an orientation-selective first stage.

In a second experiment, they examined the effects of adaptation on the subjects' abilities to both detect the presence of a moving stimulus and to perceive coherence of the plaid pattern. The premise of this experiment was that detection thresholds are a signature of early processing, such as that found in V1 and characterized psychophysically by orientation- and direction-selective adaptation (Sekuler, R. W. and Ganz, L., 1963), whereas the coherence thresholds reflected later stages of motion processing. Any differences in the adaptability of these two measures would be evidence for separate processing stages. Further, by testing for cross-adaptation, that is, effects of adapting with a 1D grating on the perception of a 2D plaid (and vice versa), they might uncover further evidence for an orientation-selective early stage. To see the logic of this, imagine a horizontal grating moving upwards as the adapting stimulus and an upward-moving coherent plaid (whose components move obliquely: up-left and up-right), as the test stimulus. If the earliest stage codes direction of motion, irrespective of orientation, then we might expect to find considerable cross-adaptation for these stimuli, because they both appear to be moving upwards. If, however, the early stage is both orientation- and direction-selective, then we would expect little cross-adaptation since such a stage would see only the components of the plaid, neither of which is horizontal or moving directly upwards. The results revealed little evidence for cross-adaptation of detection thresholds (see figure 7 of Movshon, J. A. *et al.*, 1985), but considerable cross-adaptation for coherence thresholds (see figure 8 of Movshon, J. A. *et al.*, 1985), both consistent with a two-stage model in which the early (detection) stage consists of filters that are tuned to both orientation and direction of motion.

Subsequent psychophysical experiments further supported the two-stage model of Adelson E. H. and Movshon J. A. (1982). In one experiment, Welch L. (1989) measured speed discrimination (Weber fractions) for gratings and plaids. Because the pattern and the components of a plaid move at different speeds (pattern speed is always faster than component speed, according to the cosine rule given below) and because discrimination performance varies with the baseline speed, Welch was able to ask which of the two speeds better predicted discrimination performance for plaids. The answer was clearly that the component speed, not the pattern speed, predicted discrimination performance (Welch, L., 1989). In another experiment, Derrington A. and Suero M. (1991) used the motion after-effect (MAE) to reduce the perceived speed of one of the components of a plaid stimulus. When they did this, they found that the perceived direction of the plaid, after adaptation, deviated in the direction of the nonadapted component. The deviation could be nulled by reducing the speed of the nonadapted component to match the perceived speed of the adapted component (Derrington, A. and Suero, M., 1991). Both results suggested that the visual system first estimated the motion of the plaid's components before combining them to generate the percept of pattern motion.

2.11.14 Plaid Physiology

Based on the psychophysical results with plaids, Movshon and colleagues used these same visual stimuli to characterize direction-selective neurons of the visual cortex. They recorded from both V1 and MT in anesthetized monkeys and from the homologous areas (area 17 and lateral suprasylvian cortex, respectively) in anesthetized cats. This allowed the authors to assess directly whether neurons in a given area tended to respond to the direction of the 1D

components or the 2D patterns, since, for any given stimulus these moved in different directions.

The physiological version of the plaid test was performed as follows (Figure 4). The direction-tuning curve of the neuron was first determined using a 1D sinusoidal grating, and this tuning curve was then used to make two predictions about the shape of the same cell's tuning curve to a plaid stimulus. Insofar as the cell sees only the 1D components of the plaid, its direction tuning curve should be bi-lobed (Figure 4, solid yellow line), with the peak of each lobe corresponding to the direction of plaid motion that places one of the component's direction of motion in the cell's preferred direction. For example, suppose a neuron prefers rightward motion to the grating stimulus. When tested with the plaid stimulus, the neuron's response is plotted as a function of the direction of the pattern motion. For a 120° plaid, when the pattern is moving to the right, neither of the grating components is moving in the preferred direction. However, for plaid pattern directions of either +60° or −60°, one or the other component grating will be moving in the cell's preferred direction. In contrast, if the cell sees pattern motion, the plaid-derived direction tuning curve is predicted to be identical to that obtained with the grating.[2] By correlating the actual tuning curve obtained to a plaid with each of the two predictions, the authors were able to quantify the extent to which a given neuron was responding to the direction of motion of the 1D components or the 2D pattern.

The results, like the plaid psychophysics, supported their two-stage model, and did so more directly. The investigators found that the majority of the neurons in cat area 17 and monkey V1 were of the component type (59 of 69 cells, 85%) with the remaining 10 neurons falling in the unclassed zone, corresponding to neurons for which neither prediction was significantly better than the other. Importantly, none of the neurons were classified as pattern-type. The results from macaque MT neurons were somewhat different: while a majority of the neurons were still classified as either component (40%) or unclassed (35%), a significant minority were characterized as pattern (25%). Thus V1 neurons appeared to see only the 1D motion (as predicted by the aperture problem) while at least some of those in MT were able to combine the 1D measurements into a representation of 2D velocity. This result clearly supported models of the integrationist type.

2.11.15 Integrationist Models

Accepting for the moment the notion that V1 neurons respond only to the 1D motion components, the challenge raised by the experiments of Movshon and colleagues is to explain how an MT neuron can have inputs that are component-selective and an output that is pattern-selective. An extremely simple explanation is depicted in Figure 5. Here three model MT

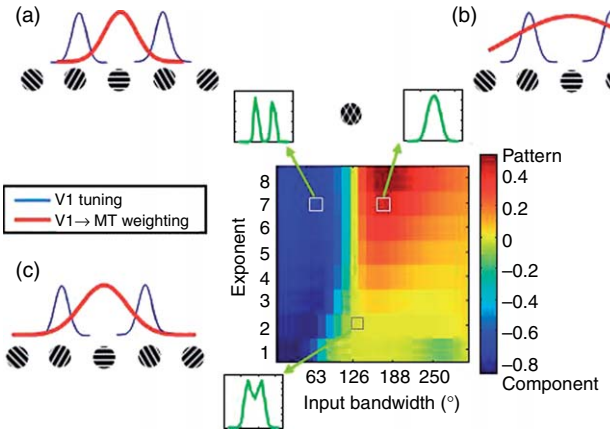

Figure 5 Three examples of hypothetical primary visual cortex (V1) tuning curves and middle temporal (MT) weighting functions. The blue tuning curves show the responses of V1 neurons to the component gratings in a plaid moving upward, which is the preferred direction of the simulated MT neuron. The red curves show the function that weights the output of the V1 neurons in the projection to MT. The central panel shows how tuning for pattern motion is affected by different bandwidths of the weighting function and different output nonlinearities. The green tuning curves show specific examples of simulated neuronal tuning to plaid patterns. The simulated plaid contained components moving in direction separated by 120°. Simulated V1 tuning bandwidth was 27° (Albright, T. D. 1984). The range of exponents was taken from DeAngelis, G. C. *et al.* (1993).

neurons receive inputs from a group of component-selective V1 neurons. For each neuron each V1 input is weighted by a Gaussian function (red curve) centered on the MT neuron's preferred direction, which in each case is upward. In Figure 5(a) the Gaussian function is sufficiently narrow that the V1 responses to the component gratings (blue curves) receive little weight when the plaid moves in the MT neuron's preferred direction. The result is a bi-lobed tuning curve (green) typical of a neuron that is classified as a component-selective. In contrast the tuning width of the MT neuron in Figure 5(b) is sufficiently large that the neuron responds to both of the plaid gratings simultaneously when the pattern direction is the same as the preferred direction of the MT neuron. The summed response to the two components is then greater than when either of the component gratings is moving in the preferred direction. In essence the MT neuron is blurring or averaging the motion inputs, so that the component directions no longer appear to be visible to it. As mentioned above, this kind of blurring is thought to have a role in eliminating motion noise, which is likely to be randomly distributed over space (Qian, N. and Andersen, R. A. 1994).

Note that the hypothetical neuron shown in Figure 5(b) would not yet meet the definition of pattern selectivity given by Movshon J. A. *et al.* (1985). The reason is that such neurons are defined as exhibiting responses that cannot be predicted from a linear combination of the responses to the components. For the neuron shown in Figure 5(b), the response to the plaid is still a linear sum of the response to the component gratings, and thus would not be considered a true pattern-selective neuron.

Nevertheless, the existence of a response peak in the pattern direction suggests that the tuning-width explanation may be a reasonable place to start. To determine if this type of explanation can be brought into line with the results of the plaid experiments, we can equip the hypothetical MT neuron with some standard nonlinearities that are known to influence the responses of all neurons. For instance, neurons have a threshold for firing spikes, and so input causing depolarization of the postsynaptic membrane that does not reach this threshold cannot be observed in the spiking activity. Furthermore, the spiking response of a neuron is generally not a linear function of its input, but rather an expansive nonlinear function. These are two uncontroversial nonlinearities that have been observed many times (Carandini, M. and Ferster, D., 2000). We will therefore consider how they might influence the responses of MT neurons to plaid stimuli.

We simulated a population of MT neurons with different bandwidths, thresholds, and expansive nonlinearities.[3] Each neuron was then classified according to a pattern index (Stoner, G. R. and Albright, T. D., 1992; Pack, C. C. *et al.*, 2001) that captured how well it conformed to the pattern prediction, taking into account the overlap between the component and pattern predictions. The central panel in Figure 5 shows the results, with red pixels corresponding to neurons that would statistically be considered pattern-selective, and blue corresponding to component-selective. As expected, increasing the bandwidth was necessary but not sufficient for generating pattern selectivity (Figure 5, bottom rows). However, when a large bandwidth was combined with either a high firing threshold (not shown) or a sharply accelerating nonlinearity, pattern selectivity emerged. Indeed using a range of parameters similar to that observed in V1 studies (e.g., DeAngelis, G. C. *et al.*, 1993) produces a distribution of component and pattern selectivities that is not unlike the distribution seen in anesthetized macaque MT. In this model, pattern and component neurons are identical, except that the former have broader tuning bandwidths than the latter (Figure 5, top rows). This can be seen clearly by comparing Figures 5(a) and 5(b), which have exactly the same nonlinearities, but differ radically in their component/pattern classification.

The nonlinearities used in the simple model described above are routinely observed in real neurons, and hence have become standard features of neural models. For example the model of Simoncelli E. P. and Heeger D. J. (1998), which will be described in more detail below, uses similar nonlinearities in its implementation of an intersection of constraints (IOC) rule to compute pattern motion. However, as we have shown here the IOC part of the model is not strictly necessary to produce pattern selectivity, although it presumably plays an important role in modeling other types of data. The strong prediction of the hypothesis shown in Figure 5 is that the pattern index would correlate on a cell-by-cell basis with each neuron's tuning bandwidth. This appears to be the case, since pattern neurons were observed to have substantially broader tuning than component neurons (Albright, T. D., 1984).[4]

A recent model has built upon a similar approach to model MT neurons, and reached a similar conclusion. Rust N. C. *et al.* (2006) developed a model in which component and pattern cells differed in tuning

bandwidth, but had similar nonlinearities. However, to model pattern cells realistically, it was necessary to add two additional features. The first was an inhibitory influence of V1 neurons on MT neurons with different preferred directions. This allowed the model to use lower (and probably more realistic) exponents than those used in the model shown in Figure 5. The second addition was strong surround suppression at the level of V1. This feature of the model is similar to the central mechanism of many selectionist models, which will be described in a subsequent section of this chapter.

2.11.16 The Intersection of Constraints, or Fourier-Plane, Model

As for the tuning-width model above, in the model proposed by Simoncelli E. P. and Heeger D. J. (1998) each V1 subunit sees only the small slice of space-time orthogonal to its preferred orientation (Figure 6), that is, it is tuned to a relatively narrow range of spatial and temporal offsets for contours of a given orientation, and it cannot discern exactly how a particular $\Delta x/\Delta t$ combination arose. Thus the model's V1 outputs suffer from the aperture problem.

The aperture problem is solved at the second stage, where MT cells collect inputs from many V1 component cells each of whose orthogonal, 1D speed measurement is consistent with a given 2D velocity. Conceptually, one can think of each 1D measurement as being consistent with a number of possible 2D velocities, all of which must fall on a line in velocity space (Figure 7, dashed lines). The intersection of any two of these constraint lines (provided the 1D measurements were made at edges having different orientations and belonging to the same object) provides the solution. As a result, this type of model is often referred to as an intersection of constraints, or IOC, model.

To see better how the IOC calculation might be carried out by a neuron, we consider an example MT cell that is to be tuned for true 2D velocity upwards at $10^\circ\ s^{-1}$ (Figure 6(a)). Such a cell would receive excitatory inputs from a family of horizontally oriented V1 cells with upwards direction preferences but with different combinations of preferred spatial and temporal offsets ranging from spatially fine subunits, say an optimal Δx of 0.1° and a Δt of 10 ms, to spatially coarser subunits, such as one with optimal values of a Δx of 1° and a Δt of 100 ms – all consistent with a speed of $10^\circ\ s^{-1}$ perpendicular to their horizontal orientation. In addition, this same MT cell would receive excitatory drive from additional $\Delta x/\Delta t$ families of V1 cells tuned to different orientations/directions but corresponding to slower preferred orthogonal speeds, according to a cosine relationship: $S_{V1} = S_{MT} * \cos(\theta_{V1} - \theta_{MT})$, where S_{MT} and θ_{MT} are the desired preferred speed and direction of the MT neuron, and S_{V1} and θ_{V1} are the corresponding directional preferences of the oriented V1 inputs. Thus, the entire range of possible orientation–velocity relationships is described by a circle in velocity space (Figure 6(b)). For our example, MT neuron, the optimal Δx's and Δt's of the family of inputs preferring right oblique orientations and upright motion would all have preferred orthogonal speeds of $7^\circ\ s^{-1}$, and, similarly, the preferred orthogonal speed of the

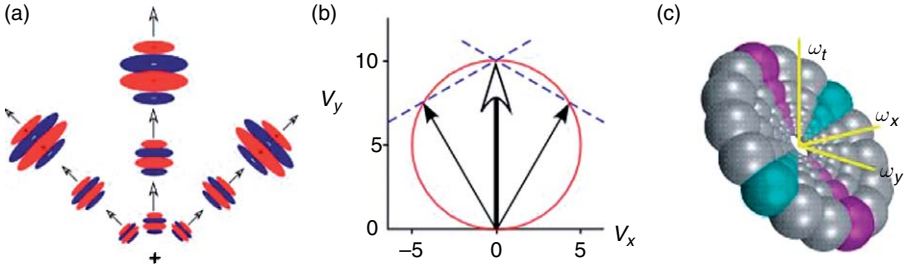

Figure 6 Integrationist model of pattern direction selectivity in middle temporal (MT) proposed by Simoncelli E. P. and Heeger D. J. (1998). (a) Partial collection of primary visual cortex (V1) inputs to a pattern cell tuned to a velocity of $10^\circ\ s^{-1}$ upwards. Each subunit corresponds to the receptive field of a V1 complex cell. (b) Velocity–space representation of the intersection of constraints (IOC) calculation. Any one-dimensional (1D) velocity measurement (solid arrows) is consistent with a range of two-dimensional (2D) velocities falling along a constraint line (dashed lines) perpendicular to its motion vector. For two such measurements made at different orientations, the 2D velocity is given by the point of intersection of the two constraint lines. Conversely, all 1D velocities consistent with a given 2D velocity (hollow arrow) fall on a circle in velocity space. (c) The frequency–space representation of the model depicted in (a). See text for additional details. (a,c) Adapted from figures 2D and 3B of Simoncelli, E. P. and Heeger, D. J. 1998. A model of neuronal responses in visual area MT. Vision Res. 38, 743–761.

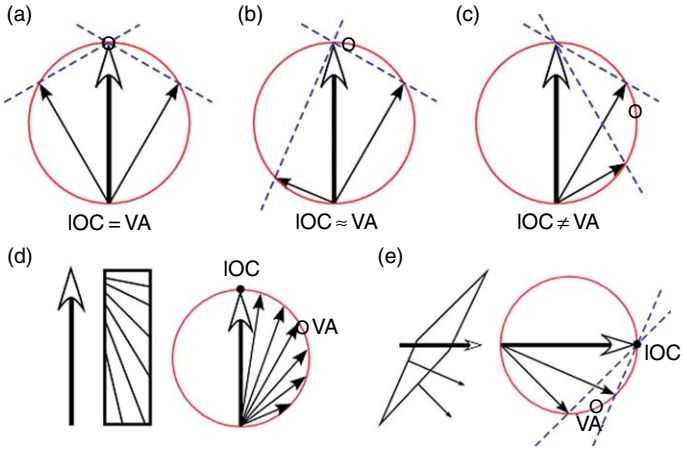

Figure 7 Velocity–space representations of different, multicomponent motion stimuli. (a) Symmetric plaids of the kind used by Adelson E. H. and Movshon J. A. (1982) in which the intersection of constraints (IOC) and vector average (VA) produce identical directions. (b) Asymmetric type I stimuli in which the two components move at different speeds. For most such stimuli, the IOC and VA yield approximately the same direction of motion, though the VA is not always perfectly accurate. (c) Type II stimuli in which the one-dimensional (1D) velocities of the two components both lie on the same side of the resultant. For these stimuli, the IOC and VA directions are quite different. (d) Type II barber poles used by Rubin N. and Hochstein S. (1993) along with the velocity–space representation of the component motion vectors. (e) Thin rhombus from Weiss, Y. *et al*. (2002), which, at low contrasts, appears to move in the VA direction.

vertically oriented V1 inputs to this cell would be $0° \text{ s}^{-1}$. The range of Δx's and Δt's within each family of V1 inputs at a given orientation confers upon the model MT cell true speed tuning (i.e., independent of the spatial composition of the stimulus) and the different families at different orientations/directions allow MT cells to solve the aperture problem and respond to the pattern direction of a plaid.

While the velocity–space construction used above is conceptually useful, in practice the model is implemented in the spatiotemporal frequency domain (Figure 6(c)). In the first stage, the Fourier-transformed visual stimulus is multiplied by the frequency-space representations of oriented Gabor filters whose output is half-squared (i.e., the negative values are clipped off and the result is squared) and normalized to produce a measure of motion energy (Adelson, E. H. and Bergen, J. R., 1985) orthogonal to the orientation of the Gabor. When plotted in the three-dimensional space comprised of two dimensions of spatial frequency (ωx and ωy) and one of temporal frequency (ωt), the selectivity of a given model V1 neuron appears as a pair of localized blobs positioned symmetrically about the origin, and the different spatial scales of the filters (corresponding to the $\Delta x/\Delta t$ families described above) fall along a line passing through the origin. In this frequency space the locus of points corresponding to a unique 2D velocity describes a plane, so a given MT cell just sums up all of the spatiotemporal blobs within the plane consistent with its particular preferred direction and speed. The plane of blobs in Figure 6(c) thus comprises the responses of V1 neurons representing eight different orientations/directions at five different spatial scales. Because the model MT neurons in stage two can be thought of as planar templates in frequency space, the IOC model has also been referred to as the Fourier-plane, or F-plane, model (Born, R. T. and Bradley, D. C., 2005).

This model has been highly successful in accounting for, not only the original plaid data that motivated it, but a number of other known MT properties, such as responses to random dots embedded in noise (Newsome, W. T. *et al*., 1989; Britten, K. H. *et al*., 1992). Subsequently, further support for this type of model came from Okamoto H. *et al*. (1999), who showed that component MT neurons have bimodal direction tuning for dots moving at high speeds, while pattern cells have bimodal tuning for bars moving at slow speeds. Both of these results are direct predictions of the F-plane model (Simoncelli, E. P. *et al*., 1996), although they are also consistent with other types of integrationist models (Kawakami, S. and Okamoto, H., 1996; Albright, T. D., 1984). The F-plane model also predicts bimodal responses in MT pattern cells for stimuli composed of overlapping dot fields, a prediction that was recently confirmed (Bradley, D. C. *et al*., 2005). Finally a direct test of the F-plane model in MT

found a population of cells that demonstrated the spatiotemporal selectivity predicted by the model (Perrone, S. A. and Thiele, A., 2001). However, these cells turned out not to be pattern cells when tested with plaids (Priebe, N. J. *et al.* 2003), as described below (see Section 2.11.18 Challenges to Integrationist Models).

2.11.17 Other Integrationist Models

There are a number of other models whose basic structure is very similar to that of the IOC model described above in that they all first indiscriminately calculate local, 1D measures of motion and then combine them nonlinearly to yield the IOC solution at a subsequent stage of the model. One source of relatively minor differences is the nature of the elementary motion detectors used at the first stage. Perhaps the most popular method is the motion energy model of Adelson E. H. and Bergen J. R. (1985), which was used by Heeger and colleagues in the model detailed above (Heeger, D. J., 1987) as well as by Grzywacz, N. M. and Yuille, A. L. (1990). Other methods include the gradient constraint method of Limb J. O. and Murphy J. A. (1975), used in the model of Fennema C. and Thompson W. (1979), and those based on scalar motion sensors described by Watson, A. B. and Ahumada, A. J. (1985) and used in the motion integration model of Ogata M. and Sato T. (1991). Similarly, the IOC calculation at the second stage can be realized in a variety of ways. We have already seen two of them in the form of the velocity–space construction, also used by Sereno M. E (1993) and Albright T. D. (1984) and the F-plane template implementation by Heeger D. J. (1987). Another way of calculating the intersection of constraint lines is to use the inverse Hough transform, and this has been featured in several other integrationist models (Fennema, C. and Thompson, W., 1979; Ogata, M. and Sato, T., 1991; Kawakami, S. and Okamoto, H., 1996). The details of these models are important – they affect the models' performance in comparison to human observers and how well it describes the response properties of neurons in V1 and MT, and they also are critical for evaluating the model's biological plausibility in terms of computations that can be carried out by neural circuits – but they are beyond the scope of this review. The issue of greater concern is to see to what extent they are consistent with the existing psychophysical and physiological data, and to compare them with models of a fundamentally different kind.

2.11.18 Challenges to Integrationist Models

As mentioned above, indirect evidence for the F-plane model comes from experiments that have confirmed the model's predictions on bimodal direction tuning. However, these same findings are predicted by other models, so they do not constitute a direct test of any particular hypothesis. A more decisive test of the F-plane model would involve stimulating MT neurons with gratings of different spatial and temporal frequencies, and measuring the extent to which neuronal responses display velocity invariance. That is, according to the F-plane model pattern-selective neurons should be selective for velocity in a manner that is largely independent of the spatiotemporal composition of the stimulus. This experiment has been done by Priebe N. J. *et al.* (2003), who found that true velocity tuning is rare in MT and, more importantly, it does not correlate in any obvious way with the pattern-component categorization (Priebe, N. J. *et al.*, 2003). In fact, velocity selectivity as hypothesized by the F-plane model is no more common in MT than in V1 (Priebe, N. J. *et al.*, 2006), suggesting that it is not related to the computation of pattern motion. Similar findings on velocity tuning were found using bars (Mikami, A. *et al.*, 1986) and small spots (Pack, C. C. *et al.*, 2006). The F-plane model thus does not appear to be consistent with the finding that the vast majority of MT neurons are capable of accurately encoding motion direction despite large changes in the spatiotemporal components that comprise the stimulus (Pack, C. C. and Born, R. T., 2001).

To the extent that integrationist models do not account for the MT data, it is useful to examine some of the models' underlying assumptions. Perhaps the strongest of these hypotheses is the notion of a purely linear first stage that measures only 1D spatial frequency components. This concept has often proven useful in vision modeling, but it is important to keep in mind its status as an approximation to the real behavior of V1 neurons. Real neurons at all stages of visual processing have a variety of nonlinear responses, some of which may be important to the integration of motion signals. A second category of models, which we call selectionist models, examines the extent to which these early nonlinearities might contribute to motion integration. Before considering

the models themselves, we will review some of the issues that motivated their conception.

2.11.19 Intersection of Constraints, Vector Average, or Feature Tracking?

The early experiments on the perception of plaid motion used component gratings whose orthogonal 1D velocities were symmetrically placed on either side of the resultant 2D pattern velocity, producing so-called symmetric type I plaids (Figure 7(a)). For such symmetrical stimuli, a simple average (or sum) of the two 1D vectors will produce a resultant vector with the same direction (though a different speed) as that produced by the IOC computation. For simplicity, we will refer to this type of computation as the vector average (VA). The experiments of Adelson E. H. and Movshon J. A. (1982) could not distinguish between these two computations. Furthermore, their stimuli contained potentially trackable 2D features, in the form of the bright blobs formed at the intersections of the two gratings. Such features could be detected by a simple operation that detects luminance maxima (Bowns, L., 1996). And since these 2D features always move in the pattern direction, this strategy cannot be easily distinguished from an IOC. While the adaptation and masking experiments (Adelson, E. H. and Movshon, J. A., 1982) argued against a feature-tracking strategy for plaids composed of sinusoidal gratings, we will see below that other, more salient, features can dramatically affect perception.

While symmetric plaids cannot distinguish between an IOC (or feature-based) computation and a VA, other stimuli can be constructed in which the component velocities either straddle the resultant asymmetrically (asymmetric type I; Figure 7(b)) or both lie to the same side of the resultant (type II; Figure 7(c)). In terms of probing the nature of the second-stage computation, type II stimuli are particularly interesting, because the perceived direction predicted by an IOC can be very different from that predicted by a VA (Figure 7(c)). In this case, the IOC computation produces the veridical direction of pattern (or object) motion, whereas the VA is inaccurate. As such it would seem to make sense for the visual system to use the IOC. Surprisingly, however, human observers misperceive the direction of motion of such stimuli under certain conditions, and they do so in the direction predicted by the VA. This was found, for example, for type II plaids of low contrast or those viewed for brief durations (Yo, C. and Wilson, H. R., 1992), for modified, type II, barber pole stimuli (Rubin, N. and Hochstein, S., 1993; Figure 7(d)), for multiple line segments each presented within a separate aperture (Mingolla, E. *et al.*, 1992), and for a thin, rhombus at low contrast (Weiss, Y. *et al.*, 2002; Figure 7(e)). For all of the above stimuli, there was a consistent direction of rigid translational motion that an IOC computation recovers. The fact that this direction was not perceived argues strongly that the visual system does not always use an IOC calculation.

Further evidence against a strict IOC computation came from experiments in which type I and type II plaids were compared with respect to their ability to interfere with the perception of a test pattern moving in the IOC resultant direction (Ferrera, V. P. and Wilson, H. R., 1987) and with respect to direction discrimination thresholds (Ferrera, V. P. and Wilson, H. R., 1990). In both sets of experiments, type II plaids behaved very differently from their type I counterparts. In particular, the type II plaids were much less effective at masking, being no more effective than their 1D component that was nearest to the resultant direction (Ferrera, V. P. and Wilson, H. R., 1987), and they yielded much higher direction discrimination thresholds that were also biased towards the direction of motion of their components (Ferrera, V. P. and Wilson, H. R., 1990). To explain their psychophysical results, Wilson and colleagues (1992) suggested a type of integrationist model, in which a VA of Fourier and nonFourier motion components is computed.

Some of these same experiments also revealed that 2D features, such as dots or line endings, had a powerful effect on the perceived motion of visual patterns. In the experiments of Rubin N. and Hochstein S. (1993), using dashed, instead of solid, lines to construct the modified barber pole stimulus dramatically changed the perceived direction of motion from the VA to veridical. In another series of experiments, they added variable numbers of randomly placed dots to the regions between the solid lines and found that even a single dot was sufficient for observers to report the true direction of pattern motion. Mingolla E. *et al.* (1992) found a similar transition from a VA of the isolated 1D elements to the true direction of pattern motion when they added 2D features such as small rectangles defining the line segment's endpoints. Finally, the classic barber pole illusion, originally described by Wallach (Wallach, H., 1935; Wuerger, S. *et al.*, 1996), is a powerful demonstration of the ability of the motion of 2D features to influence perception. In this case, the

features are the angular endings of the windowed grating, often referred to as terminators. Despite the fact that the 1D component contributes much more motion energy, the prevailing direction of 2D terminator motion along the long axis of the aperture dominates the percept.

The barber pole illusion might seem to indicate that the 1D motion signals are completely ignored by the visual system, but this is clearly not the case. The influence of 1D motion can be seen in the phenomenon of capture (Castet, E. *et al.*, 1999), which refers to the greater probability of perceiving motion in the terminator direction as the direction of the 1D signals approaches it more nearly. Other evidence for an active competition between 1D and 2D motion signals is the multistability of barber pole stimuli, which refers to the possibility of seeing one of three modal directions (long axis, short axis, or perpendicular to contour) during single brief observations (Castet, E. *et al.*, 1999) and to the fact that the perceived direction alternates randomly during prolong viewing (Wallach, H., 1935). The multistability is particularly apparent when the 2D signals are weakened by rendering them extrinsic[5] (Castet, E. *et al.*, 1999), suggesting mechanisms for computing the salience of 2D features (Shimojo, S. *et al.*, 1989).

2.11.20 Dynamics of 1D and 2D Computations

In the context of the competition between 1D contours and 2D features, perhaps the simplest way to probe motion integration psychophysically is to construct a stimulus that consists entirely of line segments moving in a direction that is not perpendicular to their orientation. As for barber poles, the contour motion is in a different direction than the motion of the line-segments' ends. This kind of stimulus was first used in psychophysical experiments by Lorençeau J. *et al.* (1993), who demonstrated that humans perceive the motion of such stimuli inaccurately when viewed for brief durations or when the lines were of low contrast. Importantly, these inaccurate percepts were not randomly wrong, but rather were systematically biased in the direction perpendicular to the edges of the line segments, as predicted by the aperture problem. This result was thus similar to those obtained with type II plaids (Yo, C. and Wilson, H. R., 1992), and strongly suggested an interesting temporal dynamic from an early VA of 1D signals to a more veridical percept at later times, produced by either an IOC or feature-based computation.

2.11.21 Bar-Field Physiology

The stimuli used by Lorençeau J. *et al.* (1993) can be readily adapted to neurophysiological experiments, and they can test many of the same hypotheses that have been addressed with plaid stimuli. Indeed from the point of view of models with a purely linear first stage, the tilted bar stimulus is simply a plaid with multiple component gratings. A crucial difference is that the tilted bar stimulus contains spatial frequency components that move in the direction of the pattern as a whole. These components always have substantially lower amplitude than the components that move perpendicular to the orientation, so under this hypothesis any neuron that accurately measures their motion must have nonlinear response properties.[6]

The response of MT neurons to tilted bar stimuli has been measured using an experimental design that dissociated stimulus orientation from direction of motion. The bars moved in one of eight directions, and on different trials they were tilted at angles of 45°, 90°, or 135° with respect to the motion direction. The 90° tilt condition served as a measure of the baseline direction tuning of each neuron, since in this case the local measurements perpendicular to the orientation were by definition correct. For the 45° and 135° conditions, local measurements would be expected to be inaccurate, and so these stimuli provided a different way to probe the ability of MT neurons to overcome the aperture problem.

Figure 8 shows the experimental results. The early responses in MT showed substantial biases for motion perpendicular to edge orientation, as would be predicted from the simple tiling model described previously. In contrast, the later responses were almost completely independent of stimulus orientation for nearly every neuron in the population.

This result differs from what one would expect based on the plaid experiments (Movshon, J. A. *et al.*, 1985). In particular, the existence of component neurons has been interpreted to mean that a substantial fraction of MT neurons have responses that can be modeled based solely on linear spatial frequency channels. This is clearly not the case for the vast majority of neurons in the Pack C. C. and Born R. T. (2001) study[7] and indeed other studies have found that all MT neurons exhibit nonlinear behavior in response to even modest stimulus manipulations (Stoner, G. R.

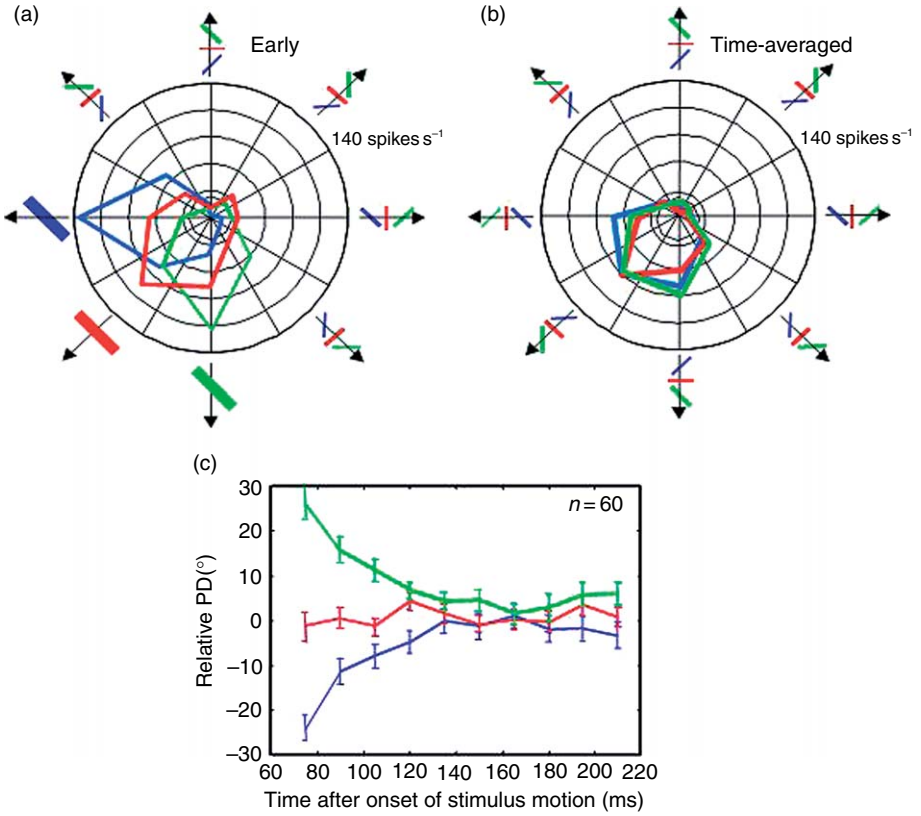

Figure 8 Response of middle temporal (MT) neurons to the bar field stimulus. (a) For a single MT neuron, the early part of the response depends on both the orientation and direction of the bar field. This neuron responds best whenever the bar has a left-oblique orientation and a leftward or downward motion component, indicating that it sees only the component of motion perpendicular to the bars. (b) The later part of the response depends only on the motion direction. (c) The transition from orientation-dependent responses to purely motion-dependent responses is evident in the population of 60 MT neurons. PD, preferred direction.

and Albright, T. D., 1992; Pack, C. C. *et al.*, 2004; Krekelberg, B. and Albright, T. D., 2005). This is not to say that linear models are incorrect – the hypothesis of linearity is after all just a way of representing the stimulus, and the responses are clearly related to the stimulus. Rather the results indicate that linear models are not sufficient to account for the behavior of MT cells, even if one grants that they may provide an accurate description of V1 outputs.

The results with bar fields did not distinguish between integrationist and selectionist models, since both would be expected to measure motion direction accurately. However, they did provide an impetus for looking for such differences in V1. This proves critical for distinguishing between the two types of models, because selectionist models would predict that selectivity for the motion of 2D features should be found in V1, while integrationist models predict that only 1D motion is represented at the first stage. Further motivation to look for a representation of 2D feature motion in V1 came from psychophysical experiments, which strongly suggested that the motion of terminators is calculated at a very fine spatial scale (Power, R. P. and Moulden, B., 1992; Kooi, F. L., 1993). A particularly dramatic illustration of this is that the barber pole illusion is completely abolished by cutting small notches in the aperture so that the direction of local terminator motion becomes the same as that of the 1D contours (Figure 9(a)).

A similar effect was seen for MT neurons in conscious monkeys (Pack, C. C. *et al.*, 2004). These investigators demonstrated that MT neurons reveal an effect similar to that of the barber pole illusion: their directional responses were dominated by the motion of the 2D terminators and not by that of the 1D contours. In fact, by testing neurons with barber poles of different aspect ratios, they were able to show that, as a population, MT neurons compute the VA of

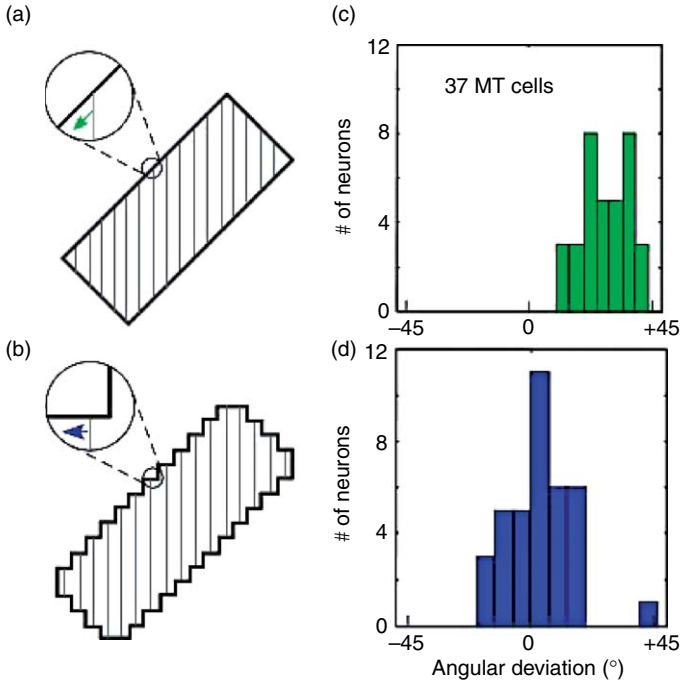

Figure 9 Effect of aperture shape on the responses of middle temporal (MT) cells. In the standard barber pole illusion (a), the dominant perceived direction of motion is parallel to the long edge of the aperture – in this case, down and to the left. Cutting notches in the aperture (b) abolishes the illusion, such that the perceived direction is now to the left, in the same direction as the one-dimensional grating. The notches have the same effect on MT cells (c) and (d). For normal barber poles (c), the direction vectors of the MT population are deviated from the grating direction toward the direction of motion of the terminators on the long axis of the aperture. (d) Cutting notches in the aperture eliminates this deviation, and the MT population now shifts back to the direction of grating motion. Adapted from figure 8 of Pack, C.C., Gartland, A.J., and Born, R.T. 2004. Integration of contour and terminator signals in visual area MT of alert macaque. J. Neurosci. 24, 3268–3280.

the two directions of terminators – those along the short and long edges of the aperture – weighted according to their relative frequencies, with little influence of the 1D signals.[8] This was measured as a deviation in the neuron's preferred direction away from the 1D and towards the 2D direction of motion (Figure 9(a)).When notches were cut in the barber poles (emulating the psychophysical experiment of Kooi F. L. (1993)) the MT population response collapsed back to the 1D direction, just as for the percept (Figure 9(b)). The most striking aspect of this result was the relative dimensions of the features: the barber poles were scaled to nearly fill the center of the MT RFs, making them, on average, 6–10° along the long axis of the aperture, while the indentations that abolished the barber pole effect were only 0.4° in length, less than one-tenth the size of the MT RF's linear dimensions. In fact, at the eccentricities tested, the indentation's dimensions were much more closely matched to RF sizes in V1 (Van Essen, D. C. *et al.*, 1984).

Similar results were also obtained with plaid stimuli. In this experiment, Majaj N. J. *et al.* (2007) first characterized MT cells using the plaid test, but with versions of plaids that were a fraction of the size of the MT RF. They next tested the same neurons with pseudoplaids that had been, in effect, pulled apart so that the two component gratings were now side-by-side instead of overlapping, yet both still well within the RF center. The effect of this manipulation was always to make the cell's direction tuning curve less patternlike, suggesting again that the 2D computation is performed locally at a spatial scale smaller than that of MT RFs.

2.11.22 Physiological Evidence for Early 2D Motion Signals

The first physiological evidence for 2D motion signals early in the cortical motion pathways had already been provided by Hubel D. H. and Wiesel T. N. (1965) who described neurons that were both direction-selective and end-stopped (or hypercomplex in their original nomenclature; Figure 10). The

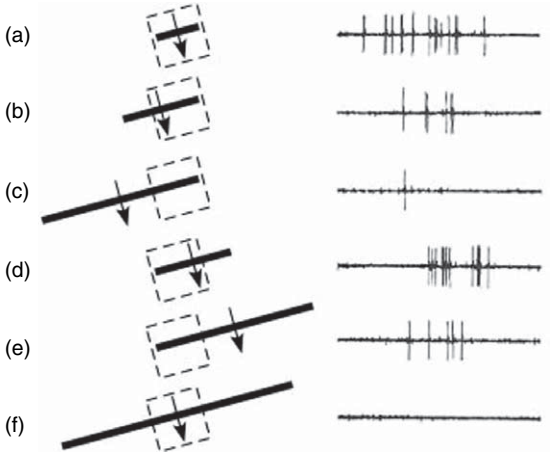

Figure 10 An end-stopped, direction-selective cell recorded by Hubel D. H. and Wiesel T. N. (1965). The neuron responds to a short bar, just covering its activating region (a), and to longer bars whose endpoints are centered over the activating region (b)–(e), but gives no response to a long bar centered over its activating region (f). Adapted from figure 17 of Hubel, D. H. and Wiezel, T. N. 1965. Receptive fields and functional architecture in two nonstriate visual areas (18 and 19) of the Cat. J. Neurophysiol. 28, 229–289.

cell responds preferentially to motion downwards (and slightly to the right), giving no response to the opposite direction of movement. Moreover, the cell is completely silent to any bar longer than the cell's tiny activating region. Such a neuron would appear to be a perfect candidate for providing 2D motion signals.[9] However, as Hubel D. H. and Wiesel T. N. only tested motion orthogonal to the orientation of the (very short) bar, they were not able to rigorously test the neuron's relative immunity to the aperture problem, nor did they demonstrate true 2D direction selectivity for line endings.

Both of these properties were subsequently demonstrated for neurons in striate cortex of alert monkeys by Pack C. C *et al.* (2003b). Figure 11a shows the RF of an end-stopped, direction-selective V1 neuron, as mapped with small spots identical to those shown in Figure 2. In this case the analysis reveals the parts of visual space to which the neuron responds (i.e., the RF). Figure 11(d) shows the same neuron's second-order subunit.[10] calculated using exactly the same method as that shown in Figure 2. Neither map shows any characteristic that would distinguish the neuron from the standard notion of a direction-selective complex cell.

Based on these maps, one can generate predictions of the same neuron's response to a second stimulus, in which the small spots were replaced with two long bars, one white and one black. In this experiment, the bars matched the neuron's preferred orientation, and were substantially longer than the RF shown in

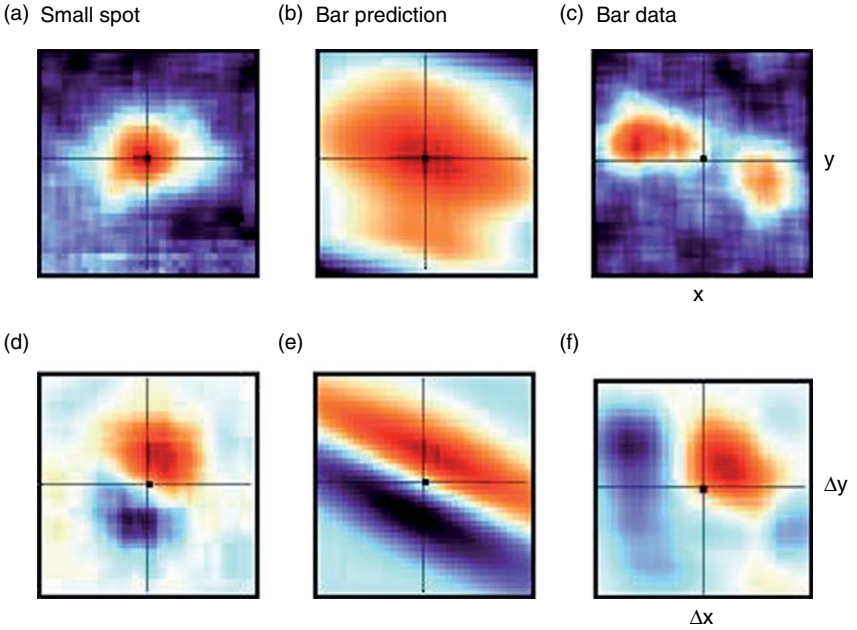

Figure 11 Subunit structure for a direction-selective, end-stopped primary visual cortex (V1) neuron. (a) The map of the receptive field obtained with small spots. (b) The predicted response to long bars flashed at different positions near the receptive field. (c) The actual map obtained with long bars. (d)–(f) As in (a)–(c), but the maps and predictions are for two-frame displacements of the long bars.

Figure 11(a). Otherwise the experiment was identical to the first one, with the bars changing position at random on each frame. The predictions, computed using convolution integrals, are shown in Figures 11(b) and 11(e). Not surprisingly, the long bar has the effect of stretching both maps along the bar's axis of orientation. This is what would be expected if the neuron viewed the long bar as simply a collection of spots like those used to generate the original maps.

The actual data, obtained using a variant of the analysis shown in Figure 2, is shown in Figures 11(c) and 11(f). The map of responses to individual bar positions, shown in Figure 11(c), reveals a characteristic signature of end-stopping: two hot spots with an intervening cold zone, which gives the maps the appearance of a dumb-bell (Figure 11(c)). One can view this map as depicting the parts of the bar to which the neuron responds best, and the two hot spots as indicating that the neuron only responses to the endpoints of the bar. The response to the center of the bar is suppressed by the mechanism that generates end-stopping, with the result that the neuron is essentially a detector of 2D features. This confirms that end-stopped neurons respond to the endpoints of long bars as was previously shown by Hubel D. H. and Wiesel T. N. (1965). In the study of Pack C. C. *et al.* (2003), the presence of end-stopping was also verified by the standard method of sweeping bars of various lengths across the RF and measuring the response of the neuron.

The data for the second-order subunit also showed a striking departure from the linear prediction shown in Figure 11(e). Rather than being smeared along the axis of bar orientation, the map shows a discrete region of activation which suggests a preference for roughly the same range of velocities as when the cell was stimulated with small spots. The cell was likely to fire an action potential in response to any two-bar sequence proceeding from up-right to down-left, corresponding to a preferred direction of 225°. This closely matched the preferred direction in the map obtained with spots, as well as the preferred direction obtained by a conventional direction tuning curve using swept bars or drifting random dots. The similarity of all three measures presumably reflects the neuron's selectivity to the bar's endpoints, because the motion of these 2D features are not influenced by the aperture problem. That this representation was truly independent of the 1D motion signals generated by the bar was shown by generating additional second-order maps using long bars that were rotated ±45° from the cell's preferred orientation. In all cases, the preferred direction indicated by the second-order map changed little, if at all.

It has not been shown that the type of end-stopped, direction-selective V1 neuron described above actually projects to MT, so it is possible that MT neurons receive only 1D motion signals from nonend-stopped cells and must use an IOC or VA to recover the 2D motion *de novo*. This seems unlikely, however, based on the known properties of neurons in 4B, which, in terms of numbers of neurons, provide over 90% of the V1 input to MT (Maunsell, J. H. and van Essen, D. C., 1983; Shipp, S. and Zeki, S., 1989). It is well established that layer 4B has a great proportion of highly direction-selective neurons (Dow, B. M., 1974; Blasdel, G. G. and Fitzpatrick, D., 1984; Livingstone, M. S. and Hubel, D. H., 1984; Hawken, M. J. *et al.*, 1988), and that most of these neurons also exhibit strong suppressive surrounds, including end-stopping (Sceniak, M. P. *et al.*, 2001). While these previous studies did not identify any of the recorded neurons as projecting to MT, it highly likely that many of them did, as the MT-projecting neurons are the largest neurons in layer 4B (Sincich, L. C. and Horton, J. C., 2003) and thus more likely to be sampled by a microelectrode than their smaller neighbors (Towe, A. L. and Harding, G. W., 1970; Humphrey, D. R. and Corrie, W. S., 1978; Lemon, R., 1984). In sum, it is highly likely that the bulk of the V1 inputs to MT originating from layer 4B are both direction-selective and strongly surround suppressed.

The finding of 2D motion selectivity in end-stopped cells suggests a reasonable explanation for the responses to bar fields in MT, but it remains unclear to what extent end-stopping can account for the observed responses to plaids. Theoretically the possibility makes sense, since most macaque V1 neurons are strongly end-stopped, and such neurons respond poorly to stimuli that contain only one orientation (Jones, H. E. *et al.*, 2001; Sceniak, M. P. *et al.*, 2001). For these neurons the component gratings in a plaid stimulus would not elicit strong responses, but the points near the intersections of the two gratings contain multiple orientations and thus might elicit stronger responses. These points move in the direction of the plaid pattern, so a simple explanation for the responses of pattern-selective MT neurons is that they receive input from V1 neurons that are themselves biased toward pattern selectivity.

Unfortunately, the end-stopping hypothesis is somewhat difficult to test with plaids, because pattern selectivity is typically defined with respect to predictions based on the responses to individual gratings.

Because a grating is defined as having only one orientation, a neuron that (by whatever mechanism) responded only to multiple orientations would be untestable by this method. In other words, a neuron that was pattern selective to the exclusion of component response would be unclassifiable. Consequently there is a bias inherent in all plaid studies towards overestimating the percentage of neurons that respond only to motion components.

Evidence against the idea of a pattern-selective projection from V1 to MT comes from Movshon J. A. and Newsome W. T. (1996), who found that V1 neurons that were identified as projecting to MT were all classified as component-type. However, the data consisted of only 12 neurons, half of which were from layer 6 where neurons appear specialized to provide 1D motion signals (Gilbert, C. D., 1977; Sceniak, M. P. *et al.*, 1999) but which provides a tiny fraction of MT's V1 input (<10%), and the degree of surround suppression present in these neurons was not reported.

The situation is further complicated by recent studies that have reported the existence of pattern-selective neurons in V1 (Tinsley, C. J. *et al.*, 2003; Guo, K. *et al.*, 2004). One group has found that, in macaque monkeys, general anesthesia appears to abolish these pattern responses (Guo, K. *et al.*, 2004). This is interesting because other groups have found that nonlinearities responsible for contextual surround effects are reduced by anesthesia (Lamme, V. A. *et al.*, 1998) and for stimuli of low contrast (Levitt, J. B. and Lund, J. S., 1997; Polat, U. *et al.*, 1998; Kapadia, M. K. *et al.*, 1999; Sceniak, M. P. *et al.*, 1999; Anderson, J. S. *et al.*, 2001; Cavanaugh, J. R. *et al.*, 2002), both of which characterized the physiological recordings of Movshon J. A. *et al.* (2003). This finding is also consistent with reports that, in MT, general anesthesia has the effect of reducing the sensitivity to pattern motion for both bar fields and certain types of plaids (Pack, C. C. *et al.*, 2001; but see Movshon, J. A. *et al.* 2003).

2.11.23 Selective Motion Integration

Integrationist models are useful for combining visual motion signals across 2D space, but a significant difficulty arises when multiple objects are present in 3D space. In this case it does not make sense to integrate across them, as they may be moving in different directions. A particularly elegant example is the case of a moving plaid stimulus, in which the two component gratings are located at different depths from the observer. Psychophysical work has shown that observers naturally segmented the two gratings to form a noncoherent percept when the depth ordering is defined by transparency (Stoner, G. R. and Albright, T. D., 1990), binocular disparity (Stoner, G. R. and Albright, T. D., 1998), surface segmentation (Trueswell, J. C. and Hayhoe, M. M. 1993; Stoner, G. R. and Albright, T. D., 1996), or occlusion (Lorençeau, J. and Shiffrar, M., 1992; McDermott, J. and Adelson, E. H. 2004). Correlates of selective motion integration based on depth segmentation were subsequently found in MT (Stoner, G. R. and Albright, T. D., 1992; Duncan, R. O. *et al.*, 2000; Thiele, A. and Stoner, G. 2003; Pack, C. C. *et al.*, 2004) and in area posteromedial lateral suprasylvian cortex (PMLS) of the cat (Castelo-Branco, M. *et al.*, 2000). These observations suggest that motion signals are identified early in visual processing and selected for integration based in part on their relative depths.

2.11.24 Theoretical Considerations: Redundancy Reduction

Another important source of motivation for selectionist models was a line of thinking, dating back to Attneave F. (1954) and Barlow H. (1961), which considered the goal of early sensory processing to be a reduction in redundancy of the primary sensory information, using principles developed by Claude Shannon in his seminal work on information theory (Shannon, C. E., 1948; Shannon, C. E. and Weaver, W., 1963). One of the important ideas that emerged from this field was the notion that regions of the image that were uniform in space and time were highly redundant and should be ignored in favor of regions of change. From this perspective, features of retinal RFs can be thought of as performing the mathematical operation of differentiation of the image luminance function with respect to various parameters, including: (1) visual space, observed as the RF property known as center-surround opponency (Kuffler, S. W., 1953; Hartline, H. K. and Ratliff, F., 1957), (2) time, manifest as adaptation (Hartline, H. K., 1941), (3) space–time, seen as sensitivity to movement (Hassenstein, B. and Reichardt, W., 1956; Reichardt, W., 1961; Barlow, H. B. and Levick, W. R., 1965), and iv) chromaticity, as evidenced by color opponency (Svaetichin, G. and MacNichol, E. F., Jr., 1959). Likewise, once a representation of the local orientation of contours has been performed by the cortex (Hubel, D. H. and Wiesel, T. N., 1962), one can construct a derivative for

orientation with respect to visual space, an operation which would identify regions of high curvature or other 2D features, which, as it turns out, are highly informative about shape (Attneave, F., 1954; Hubel, D. H. and Livingstone, M. S., 1987; Dobbins, A. *et al.*, 1989). In addition, as described above, such a representation can be further elaborated upon to compute the motion of 2D features and thus solve the aperture problem (Pack, C. C. *et al.*, 2003b). This is the basic approach of many selectionist models.

2.11.25 Selectionist Models

The theoretical considerations of forming efficient representations, combined with the psychophysical and physiological observations demonstrating the potency of the motion of terminators, have yielded a variety of models that we term selectionist. The central idea behind these models is that not all local motion vectors are treated equally. Rather, regions of redundant (and ambiguous) 1D motion vectors, such as those emanating from edges, are filtered out or, put another way, highly informative regions, such as those emanating from corners or line-endings, are selected prior to integration.

A key distinguishing feature of these models is how they have implemented the selection process. One approach, championed by Barth and colleagues (Zetzsche, C. and Barth, E., 1990; Barth, E., 2000) uses a geometric formulation of the luminance function as a hypersurface, and the operation of selecting regions of curvature (as measured by the Riemann tensor), to effectively model the kind of end-stopped, direction selective cells shown in Figures 10 and 11 and thus directly represent 2D velocity. The important point about these models is that they have spatial filters that respond selectively to image regions that contain multiple orientations. There are many ways to design such an operator, but as pointed out by Barth and colleagues all of them must involve nonlinear operations, the simplest nonlinearity being multiplication (Zetzsche, C. and Barth, E., 1990).

Along these lines, Skottun B. C. (1998; 1999) developed neuronal models that simply multiply the responses of orientation-tuned linear filters to arrive at selectivity for 2D features. This operation is sufficient to reproduce many of the results on both end-stopping (Skottun, B. C., 1998) and plaid tuning (Skottun, B. C., 1999). The multiplication operation is used for mathematical convenience, but in principle it could be approximated by any number of the standard nonlinearities known to affect neuronal responses (Tal, D. and Schwartz, E. L., 1997).

Another important model was put forward by Nowlan S. J. and Sejnowski T. J. (1995), and it is selectionist in spirit, even though the selective calculation is nominally performed at the MT stage of the model. In their case, the nonlinear step selects regions of change in local motion vectors by simulating MT neurons with suppressive surrounds (Allman, J. *et al.*, 1985). Such neurons are inhibited when motion is in the same direction in both center and surround, so they respond poorly, if at all, to the motion of 1D contours. This selectivity network then retinotopically gates a second, parallel integration network that pools the motion signals from the selected regions (Figure 12). Thus, for example, for a moving square, MT neurons in the selection network having RF centers overlying the contours respond weakly because there are similar directions of motion in both their RF centers and surrounds.

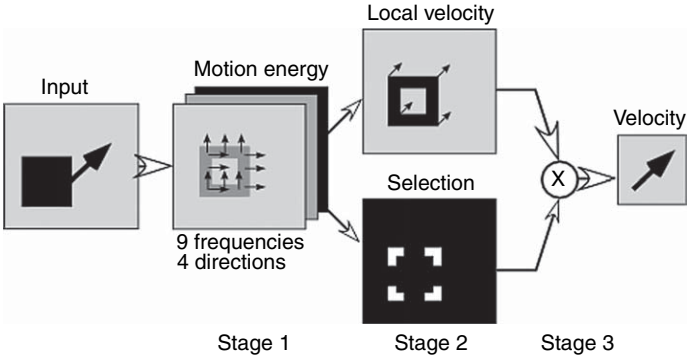

Figure 12 Selectionist model proposed by Nowlan S. J. and Sejnowski T. J. (1995). See text for details. Adapted from figure 2 of Nowlan, S. J. and Sejnowski, T. J. 1995. A selection model for motion processing in area MT of primates. J. Neurosci. 15, 1195–1214.

Surround-inhibited neurons with RF centers positioned at the corners are not effectively suppressed, resulting in a selection of these regions for pooling by the integration network, effectively producing feature tracking. The same logic allows the model to effectively track the motion of 2D intersections in plaid stimuli.

2.11.26 Hybrid Models

Thus the selectionist category of models can be thought of as instantiating a kind of feature tracking, whereas the integrationist models implement an IOC computation. The perceptual data, however, suggest that a single computational strategy will not suffice: under some circumstances, an IOC or feature-tracking rule seems to be in effect, whereas for others, a VA best describes the integration process. This lack of parsimony has motivated computational modelers to seek more general descriptions that can better accommodate the variety of behaviors. A notable recent effort by Weiss Y. *et al.* (2002) essentially embeds many of the features of the IOC calculation in a Bayesian model. The Bayesian calculation involves weighting the first-stage inputs according to the uncertainty associated with the local motion measurement, with the result that 2D features strongly influence the velocity–space calculation in the second stage. Because the velocity–space constraints are subject to noise, the constraint lines are more or less fuzzy depending on the contrast of the stimulus. The stimulus-based evidence is multiplied by a second probability distribution that a priori favors slow speeds (a symmetrical 2D Gaussian centered about the origin in velocity space) in order to obtain the posterior probability in favor of a given 2D object velocity.

These properties endow the model with a rather intuitively appealing behavior that explains much of the existing psychophysical data (Weiss, Y. and Adelson, E. H., 1998). The two key observations are, (1) that the VA percept tends to dominate in conditions where the stimulus-based evidence is relatively weak (low contrast, short duration, or a narrow range of component orientations), and (2) the velocity predicted by the VA is always slower than that of the IOC. The model's behavior can be understood in terms of the relative influence of the prior favoring slow speeds. When the stimulus-based evidence is strong, the prior has little effect and the result is essentially an IOC. When the stimulus-based evidence is weak, the likelihood functions are dim and fuzzy, and the prior has a relatively large effect, pushing the result towards a slower speed, which approaches the VA.

In a related study, Stocker A. A. and Simoncelli E. P. (2006) used a speed discrimination task to estimate the slowness prior and the likelihood functions at different speeds and contrasts for individual observers. Their measurements revealed significant differences between the measured functions and those assumed by the model of Weiss Y. *et al.* (2002). For example, the slowness prior was not well described by a Gaussian, but rather flattened out at higher speeds, and the inverse relationship between the width of the likelihood function and stimulus contrast was different for different observers. It will be important to test whether such differences can be used to better account for individual performance on other motion integration tasks, such as those used by Weiss Y. *et al.* (2002).

Weiss Y. *et al.* (2002) did not hypothesize a physiological basis for the model's computations, but many of the phenomena reported are also consistent with physiological properties of end-stopped V1 cells. End-stopping (and nonlinear contextual effects in general) is weak or nonexistent for stimuli of low contrast (Levitt, J. B. and Lund, J. S., 1997; Polat, U. *et al.*, 1998; Sceniak, M. P. *et al.*, 1999) and takes time to manifest itself in the neuronal response (Pack, C. C. *et al.*, 2003b). Under such circumstances, the local velocity measurements made in V1 are essentially 1D, as postulated by integrationist models, although the perceived direction is more similar to a VA than an IOC. For high-contrast stimuli end-stopping is effective, allowing 1D motion signals to be filtered out, thus emphasizing the veridical velocity of 2D features. Both of these observations are at least qualitatively consistent with the Bayesian computation described by Weiss Y. *et al.* (2002).

2.11.27 Future Challenges

While there has been much speculation about the role of various direction-selective neurons in motion integration and the solution to the aperture problem (Albright, T. D., 1984; Movshon, J. A. *et al.*, 1985; Pack, C. C. *et al.*, 2003b), there has been a complete lack of experiments in which these neural signals are directly compared to perceptual reports. For example, while Pack C. C. *et al.* (2003b) demonstrated that end-stopped, direction-selective neurons in V1

could, in principle, provide faithful 2D velocity measurements of features, there is no direct evidence that such neurons are actually used by perceptual systems (or even that these neurons project to MT, though, statistically, many are likely to do so). Similarly, the evidence that V1 neurons projecting to MT provide only 1D motion information (Movshon, J. A. and Newsome, W. T., 1996) cannot be considered definitive given the small sample size, the considerable oversampling of layer 6 neurons, which are known to prefer long bars (Gilbert, C. D., 1977; Sceniak, M. P. *et al.*, 2001), and the aforementioned shortcomings of the plaid test for character-izing end-stopped neurons. What is needed is a demonstration of which neurons are actively contributing to a given percept at a given time. Such evidence would need to consist of trial-by-trial correlations between the activity of these neurons and the choices of the monkey on a suitable perceptual task (Parker, A. J. and Newsome, W. T., 1998). For example, if pattern cells are important for the perception of coherent motion, then, for ambiguous plaid stimuli for which the animal may report either coherence or transparency, one would expect pattern cells to fire at higher rates during trials on which the animal reports coherence. An inverse relationship would be predicted for component cells. Such measures of choice probability (Britten, K. H. *et al.*, 1996) would strongly support the proposed roles of these neurons. Furthermore, insofar as there is spatial clustering of pattern or component neurons in MT or some other visual structure, microstimulation experiments could be used to attempt to bias an animal's reports in predictable ways, as has been done for perceived direction of motion in random dot displays (Salzman, C. D. *et al.*, 1990; 1992).

Both a challenge and a potential boon to studies linking neurophysiology to percepts of motion integration is the fact that many of the stimuli used to study it are perceptually bi- or even multistable. This is true of both plaids (Stoner, G. R. and Albright, T. D., 1996; Hupé, J. M. and Rubin, N., 2003) and barber poles (Rubin, N. and Hochstein, S., 1993; Castet, E. *et al.*, 1999). For example, prolonged viewing of plaid stimuli produces spontaneous perceptual transitions between coherence and transparency (Hupé, J. M. and Rubin, N., 2003), and this is true even for plaids whose intersection luminance values are not consistent with transparency (see Relevant Websites section). Such phenomena argue for an active, ongoing competition amongst local motion cues and will present future models with challenges similar to those encountered by models of binocular rivalry (Leopold, D. A. and Logothetis, N. K., 1999). Furthermore, the plaid multistability (Hupé, J. M. and Rubin, N., 2003) and the profound influence of shape and occlusion cues on the integration of motion (Lorençeau, J. and Shiffrar, M., 1992; Lorençeau, J. and Alais, D., 2001), underline the fact that integration and segmentation are tightly linked, even at early stages of visual processing.

In fact, relatively few motion models address the complications that arise when the visual input contains multiple objects. In such cases motion integration appears to be influenced by a mechanism that performs segmentation, presumably to avoid integrating over multiple objects or surfaces (Shimojo, S. *et al.*, 1989). The segmentation system has proven difficult to model, in part because it is influenced by nonmotion cues, especially perceived depth as defined by retinal disparity, T-junctions, or transparency. Most segmentation models involve the explicit detection of motion boundaries based on depth cues, along with the smoothing of motion signals across individual objects or surfaces (Nowlan, S. J. and Sejnowski, T. J., 1995; Koechlin, E. *et al.*, 1999; Lidén, L. and Pack, C., 1999; Bulthoff, H. *et al.*, 1989; Grossberg, S. *et al.*, 2001; Bayerl, P. and Neumann, H., 2004).

The smoothing in these models is often accomplished by a winner-take-all interaction of motion signals across networks of neurons with small RFs. This process is motivated by the perceptual observation that objects appear to move rigidly, despite the presumed diversity in local motion measurements. That is, each part of an object appears to move in the same direction, even when small RFs are reporting different velocities. However, evidence for this kind of smoothing process in V1 has not been found (Pack, C. C. *et al.*, 2004), even for stimuli that should engage the perceptual winner-take-all mechanism. In fact for barber-pole stimuli the responses in MT can be estimated with reasonable precision based on a local end-stopping procedure observable at the level of individual V1 neurons (Pack, C. C. *et al.*, 2004). However, neither the V1 nor the MT responses appear to be entirely consistent with perceptual observations, suggesting that it may make sense to start the search for neural correlates of percep-tual smoothing in regions of the cortex beyond V1 and MT.

2.11.28 Final Thoughts

As we have tried to emphasize, the existing evidence suggests that under some circumstances observers

perceive motion that is consistent with the standard integrationist model (Simoncelli, E. P. and Heeger, D. J., 1998). In contrast, there are many exceptions in the psychophysical literature, and the results of physiological tests of the model have been equivocal at best.

Evidence for 2D feature selectivity in V1 has been found in a few studies, although it is not clear how this selectivity influences MT responses. In this regard a significant problem is the lack of a standard selectionist model that can be meaningfully compared to the standard integrationist model. While many selectionist models exist, they tend to be substantially more complicated than the integrationist models discussed here, and as a result the predictions are less clear, rendering a detailed comparison problematic. Thus an important avenue for future research will be the development of a standard selectionist model. There is no reason why this cannot be done, since as we have pointed out many of the core computations are the same in both types of models.

Endnotes

[1] (Under certain conditions, such as when the components are configured to simulate transparent occlusion, even plaids with identical components can fail to cohere (Stoner *et al.*, 1990).)

[2] Even though the pattern direction would be the same as the grating direction under the plaid prediction, there is no good reason why the tuning curves should be identical. They are, after all, quite different stimuli with different perceptual properties. Nevertheless, it is an intuitively simple way to set up the test.

[3] The model's response to a component grating moving in direction d is given by

$$\left[\left[\left[\sum_i g(p_i - d)h(P - p_i)\right] - \theta\right]^+\right]^n$$

where g is a Gaussian function that describes the ith V1 neuron's direction tuning as a function of preferred direction p_i, h is another Gaussian that weights V1 inputs according to the MT neuron's preferred direction P, and θ is a threshold.

[4] The MT neurons described in Albright T. D. (1984) were categorized as belonging to type I or type II, the latter having broader tuning than the former. It was subsequently shown that these two categories corresponded to component and pattern neurons, respectively (Rodman, H. R. and Albright, T. D., 1989). The same explanation, based on differences in tuning bandwidths, also applies to the observed differences in orientation tuning preferences between pattern and component neurons (Rodman, H. R. and Albright, T. D., 1989).

[5] Extrinsic terminators are created by using binocular disparity or other occlusion cues to indicate that the grating endings are accidents of occlusion (Shimojo, S. *et al.*, 1989) and therefore not likely to belong to the moving object. Two distinguish the two types of terminators (those belonging to an object versus those that are created by occlusion) psychophysicists refer to intrinsic and extrinsic terminators, respectively. This classification, though useful, is undoubtedly too simple. Experiments by Castet E. *et al*. (1999) indicate that there may be different degrees of extrinsicness.

[6] An alternative possibility is that a linear neuron could be selective for the high spatial frequencies found near the endpoints of the moving edge. However, this does not appear to be the case for MT neurons, which generally prefer low spatial frequencies.

[7] It has often been argued that the time course observed in this experiment constitutes evidence for linear responses in MT, since the motion components moving in the global stimulus direction are low in amplitude, and hence might be expected to have longer latencies. While it is entirely possible that the 2D features are processed more slowly than 1D features, the stronger hypothesis of linearity merely begs the question of why the low-amplitude component dominates the neuronal response.

[8] Since the direction of the 1D grating motion was always 45° from the direction of either set of terminators, these experiments did not test for the influence of grating direction (capture) found psychophysically by Castet E. *et al*. (1999).

[9] Another compelling example of such a neuron is shown in one of Hubel and Wiesel's now-classic movies (see Relevant Website section).

[10] Technically, both types of maps are second-order subunits, since the response to the individual spots is independent of contrast. To avoid confusion we continue to refer only to the motion maps (Figures 11(c) and 11(f)) as second-order subunits.

Glossary

curl The local rate of rotatory flow at a point in the flow field.

deformation (def) The local rate of shear along two orthogonal axes at a point in the flow field.

differential motion Motion parallax between points at different depths within a local neighborhood of the visual field.

divergence (div) The local rate of expansion at a point in the flow field.

expansion Informally refers to a radial flow. Technically, the rate of expansion is characterized by the divergence (div). Note that the highest rate of expansion (maximum div) is not at the focus of expansion, where div is zero.

extraretinal signals Efferent, proprioceptive, or vestibular signals that are produced by eye or head movements.

focus of expansion (FOE) The fixed point at the center of a radial flow pattern. The divergence at the focus of expansion is zero.

heading The observer's instantaneous direction of translation. If the observer is traveling on a straight path, the heading direction coincides with the path direction; if traveling on a curved path, the heading direction is tangent to the path.

lamellar flow A pattern of parallel or laminar flow, in which the vector directions are parallel and of equal magnitude. Sometimes called translational motion or planar motion.

motion parallax Relative motion between environmental points at different depths produced by observer translation. Local motion parallax or differential motion, is defined within a neighborhood of the visual field ($\sim 15^{\circ}$), global motion parallax may be distributed widely across the visual field.

optic array The pattern of light reflected from environmental surfaces to a point of observation. (More generally, the volume of light reflected from surfaces to all potential points of observation, filling the medium.)

optic flow The motion pattern produced at an eye that is moving relative to environmental surfaces. The eye may be moving with respect to stationary

surfaces, or surfaces may be moving with respect to a stationary eye.
path The observer's trajectory over time.
radial flow A flow pattern in which the velocity vectors radiate, expand, or diverge outward from a focus of expansion.
retinal flow The optic flow pattern projected onto the surface of the retina. Whereas optic flow is purely radial, retinal flow can have an added rotational component due to eye rotation.
rotary flow A flow pattern that rotates around a fixed point. Sometimes called rotational motion. The rate of rotary flow is the curl.
rotational component The component of retinal flow produced by observer rotation, a solenoidal flow pattern. Observer yaw or pitch generates a lamellar flow pattern, roll or torsion about the line of sight generates a rotary flow pattern.
self-motion Movement of the observer. Instantaneously described as the sum of a translation and a rotation, each having a direction and a speed.
solenoidal flow A flow field without sources or sinks (such as a focus of expansion or contraction).
time-to-contact The time remaining before a moving observer hits an environmental surface (or vice versa).
translational component The component of retinal flow produced by observer translation, a radial flow pattern.

2.12.1 Introduction

When an observer moves through the environment, a pattern of motion is generated at the eye known as optic flow. The term was introduced by Gibson J. J. (1950) in order to generalize Helmholtz's notion of motion parallax to a motion field produced by the surrounding environment. The concept played a key role in the development of Gibson J. J.'s (1979) ecological approach to perception, which emphasizes the richness of information available in natural environments and the biological function of vision in guiding adaptive behavior. Optic flow provides a primary example of a higher-order variable that both specifies complex environmental relations and can reciprocally be used to control action. In particular, flow patterns contain information about the observer's self-motion, time-to-contact with objects (Pepping, G. J. and Grealy, M. L., 2007), the motions of other objects (Burr, this volume), and the three-dimensional (3D) shape and layout of environmental surfaces (Todd, J. T., 1995; Domini, F. and Caudek, C., 2003; Siegel, R. M. this volume) and are used to control locomotion (Warren, W. H. and Fajen, B. R., 2004). In this chapter, I focus on human perception of self-motion from optic flow; the neural basis for the detection of flow patterns is reviewed in depth elsewhere (Duffy, C. J., 2004; Raffi, M. and Siegel, R. M., 2004; see Chapter Cortical Processing of Visual Motion).

2.12.2 The Optic Flow Field

Optic flow is the pattern of motion produced at an eye that is moving relative to environmental surfaces. It is commonly represented by an instantaneous velocity field, in which each vector corresponds to the optical motion of a point in the environment. (This is only a partial description because it leaves out such properties as optical acceleration, optical trajectories, dynamic occlusion, and so on.) Given that any rigid motion can be instantaneously decomposed into a translation and a rotation, it follows that the flow pattern projected on the moving retina has two corresponding components: a translational component of radial flow due to translation of the observer (Figure 1(a)) and a rotational component of solenoidal flow due to rotation of the observer (Figure 1(b)). The problem I consider is how the visual system can determine self-motion from such flow patterns.

2.12.2.1 Translational Component

Translation of the eye on a straight path generates a radial flow pattern (Figures 1(a) and 2(a)), in which the vectors radiate outward from a focus of expansion in the direction of travel or heading and converge to a focus of contraction in the opposite direction. The radial pattern formed by the directions of the vectors depends solely on the observer's direction of travel and is independent of the distance of environmental

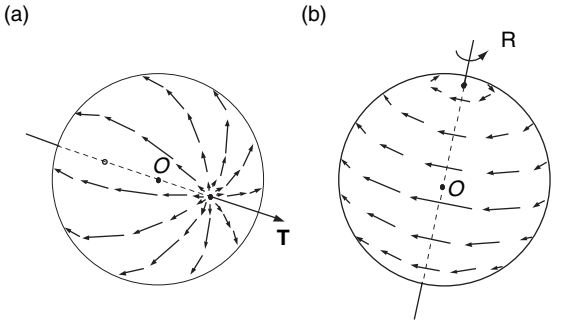

Figure 1 The retinal flow field, as projected on a sphere that moves with the eye; vectors correspond to the optical velocity of a point in the environment. (a) Translational component due to observer translation along the axis, with a focus of expansion in the direction of travel and a focus of contraction at the opposite pole. (b) Rotational component due to eye rotation about the axis, yielding solenoidal flow without sources or sinks. Reprinted from Warren, W. H. 1998. The State of Flow. In: High-Level Motion Processing (*ed*. T. Watanabe), p. 315. MIT Press, copyright 1998 by MIT Press.

surfaces. Hence, it uniquely specifies the current heading direction. On the other hand, the magnitude of each vector depends on its visual angle from the focus of expansion, the observer's speed of travel, and the distance of the corresponding point in the environment. Thus, flow magnitudes carry information about relative depth and are also correlated with the observer's heading.

In principle, determining heading from the radial flow pattern is straightforward. Any pair of vectors can be triangulated to determine their common point of origin, and doing so for many pairs yields a reliable estimate of the focus of expansion. The flow field is thus highly redundant and supports a robust heading estimate in the presence of noise, although biases result if the focus itself is not in view. This suggests a process of spatial integration in which heading is determined by pooling over many vectors in a flow pattern.

2.12.2.2 Rotational Component

When the observer rotates via either an eye or head movement, the resulting retinal flow pattern is solenoidal, that is, without sources or sinks (Figure 1(b)). Specifically, yaw or pitch of the observer generates a lamellar or parallel flow pattern (Figure 2(b)), whereas roll about the line of sight generates a rotary flow pattern. The rotational component of flow is

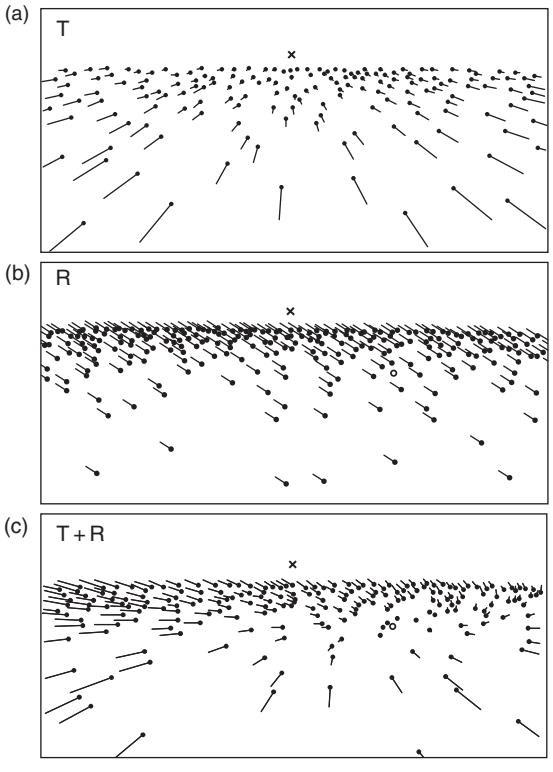

Figure 2 The rotation problem. (a) Translational component of retinal flow for a ground plane due to travel toward the X, yielding a radial flow pattern. (b) Rotational component of retinal flow due to eye rotation about a diagonal axis, yielding lamellar flow in the opposite direction. (c) Retinal flow during combined translation and rotation, due to travel toward the X while pursuit tracking the O on the ground plane. The flow field in (c) is the vector sum of those in (a) and (b). Reprinted from Warren, W. H. and Hannon, D. J. 1990. Eye movements and optical flow. J. Opt. Soc. Am. A 7, 160, copyright 1990 by Optical Society of America.

independent of distance and carries information about the observer's rotation. In particular, the vector directions depend entirely on the axis of rotation, and hence specify the observer's rotation direction. The vector magnitudes depend on their visual angle from the rotation axis and the speed of rotation, and hence specify the observer's rotation rate. Spatial integration over the flow pattern would thus permit the determination of the direction and speed of observer rotation.

2.12.2.3 Combined Translation and Rotation

When the eye is translating, the direction of heading is specified by the radial pattern of optic flow. But the

optic flow must be detected by a moving eye in a moving head, and observer rotation alters the flow pattern on the retina. When the eye is simultaneously translating and rotating, the retinal flow pattern is the vector sum of the corresponding translational and rotational components (Figure 2(c)). A pursuit eye movement induced by fixating a point in the environment, for example, annihilates the focus of expansion in the heading direction and creates a new singularity at the fixation point, as illustrated in Figure 2(c). How, then, can the visual system disentangle the translational and rotational components of retinal flow to recover the instantaneous heading direction? This has come to be known as the rotation problem in heading perception.

It is worth noting that the flow pattern on the retina is usually radial. About 60% of the time, walkers exhibit travel gaze fixation, in which the gaze direction is fixed relative to the heading direction, without pursuit movements (Patla, A. E. and Vickers, J. N. 1997; 2003). However, the rest of the time they tend to fixate obstacles, targets on the ground, or the locomotor goal, often inducing pursuit rotations.

Fortunately, as long as the environment has 3D structure, the retinal flow contains sufficient information to solve the rotation problem in principle. Specifically, observer translation is specified by the motion parallax between points at different depths, whereas observer rotation is specified by the common lamellar motion across the visual field. But with little depth structure, as in the case of a frontal plane with a small field of view, there is little motion parallax and a pseudofocus of expansion appears at the fixation point (Figure 3). Extraretinal signals about eye and head movements could also be used to determine the rotation and contribute to recovering observer translation.

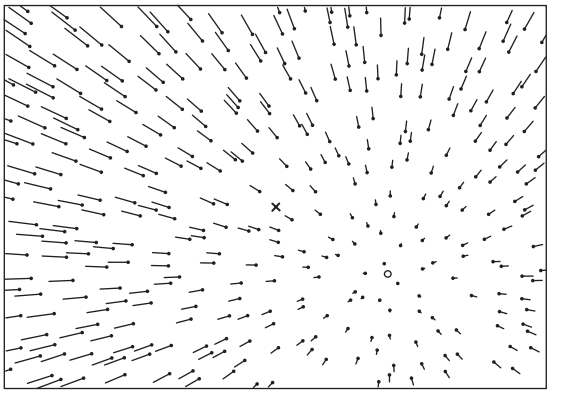

Figure 3 Special case of a frontal plane. Retinal flow during translation toward the X while rotating about a diagonal axis to track the O, yielding a pseudofocus of expansion at the fixation point. With a small field of view, there is little motion parallax across the display because the distance of the surface from the eye changes very little. Reprinted from Warren, W. H. and Hannon, D. J. 1990. Eye movements and optical flow. J. Opt. Soc. Am. A 7, 160. copyright 1990 by Optical Society of America.

2.12.3 Perception of Self-Motion

We now turn from the properties of the flow field to consider empirical data on perceiving self-motion.

2.12.3.1 Perception of Translational Heading

Psychophysical results demonstrate that heading can be perceived from radial optic flow patterns with an accuracy better than 1° of visual angle (Warren, W. H. *et al.*, 1988). In such experiments, participants view random-dot displays of radial flow with either stationary or free fixation and judge the direction of self-motion. Consistent with the independence of radial flow from distance, heading accuracy is comparable with different 3D scenes, including a ground plane, a frontal plane, or a cloud of dots. It remains high when the vector magnitudes are randomized, leaving only the radial pattern, but not when vector directions are randomized (Warren, W. H. *et al.*, 1991a). Consistent with the notion of spatial integration, heading judgments improve with the number of dots in the display (Warren, W. H. *et al.*, 1988) and are robust to added noise in vector directions (Warren, W. H. *et al.*, 1991a). Moreover, judgments of motion direction in displays of radial, rotary, and lamellar flow improve as the area of coherent motion increases, indicative of spatial summation over visual angles up to 72° (Burr, D. C. *et al.*, 1998).

The psychophysical evidence suggests that there are independent neural mechanisms sensitive to radial, rotary, and lamellar flow, either at the single-cell or at the population level. Judgments of expansion in spiral flow patterns that combine radial and rotary motions are comparable to those for radial flow patterns alone (and vice versa) (Freeman, T. C. and Harris, M. G., 1992; Barraza, J. F. and Grzywacz, N. M., 2005), and the same holds for combinations of radial or rotary motion with lamellar motion (Kappers, A. M. L. *et al.*, 1994; 1996; Te Pas, S. F. *et al.*, 1996).

These behavioral data cohere with the results from single-cell recordings in primate visual cortex. The dorsal medial superior temporal area (MSTd) contains cells selective for expansion/contraction, rotary flow, and lamellar flow (Saito, H. *et al.*, 1986); a majority of cells respond to two or three of these individual patterns (Duffy, C. J. and Wurtz, R. H., 1991a), and there is evidence for intermediate units tuned to spiral flow (Graziano, M. S. A. *et al.*, 1994). Such cells have large receptive fields up to 65° in diameter, exhibit stronger responses to larger flow patterns, and are position invariant, consistent with spatial integration of local motions (Tanaka, K. and Saito, H., 1989; Duffy, C. J. and Wurtz, R. H., 1991b; Lagae, L. *et al.*, 1994). Moreover, 90% of expansion units have receptive fields with a preferred focus of expansion (Duffy, C. J. and Wurtz, R. H., 1995; Raiguel, S. *et al.*, 1997), and microstimulation in MSTd biases the heading judgments of macaque monkeys (Britten, K. H. and Wezel, R. J. A. v., 1998). Although some expansion cells prefer an increasing speed gradient from center to periphery (Duffy, C. J. and Wurtz, R. H., 1997), eliminating the speed gradient has a far smaller impact on a cell's response than eliminating the radial pattern of directions (Tanaka, K. *et al.*, 1989). These results suggest a distributed coding of the focus of expansion in MSTd, although further processing of optic flow takes place higher in the dorsal pathway, including the ventral intraparietal area (VIP), area 7a, and the superior temporal polysensory area (STPa).

In sum, the evidence indicates that the direction of heading can be accurately perceived from radial flow patterns, and neural substrates for the extraction of radial, rotary, and lamellar flow appear to be present in the primate visual system.

2.12.3.2 Perception of Rotation

The psychophysical data on the perception of observer rotation come largely from the literature on circular (yaw) vection, a visual illusion of self-motion produced by a striped drum rotating about a stationary observer. As expected from the flow field analysis, the perceived speed of complete vection closely corresponds to that of the visual display over a wide range, up to a saturation velocity of about $120° s^{-1}$ (Brandt, T. *et al.*, 1973). Surprisingly, however, perceived speed also increases with the perceived distance of the display (Wist, E. R. *et al.*, 1975), contrary to the independence of the flow magnitude from distance. However, yaw rotation may be partially perceived as lateral translation of the observer, due to the similarity of the flow patterns generated with a 2D surface; tests of a 3D display with motion parallax are required. To my knowledge, there are no data on the perceived direction (axis) of self-rotation.

It is suggestive that most MSTd cells respond to lamellar motion, with large receptive fields, direction selectivity, and broad tuning to the overall speed of motion (Saito, H. *et al.*, 1986; Tanaka, K. and Saito, H., 1989; Orban, G. A. *et al.*, 1995). Moreover, many of these cells also encode pursuit eye movements, with a preferred pursuit direction that is on average opposite the preferred flow direction (Komatsu, H. and Wurtz, R. H., 1988). These characteristics are appropriate for the detection of flow patterns produced by eye or head rotation.

2.12.3.3 Decomposing Translation and Rotation

When one walks on a straight path while making a pursuit eye movement, the eye is simultaneously translating and rotating, and the retinal flow pattern corresponds to the sum of these two components (Figure 2). How might the visual system decompose this complex flow pattern to recover the observer's instantaneous heading and self-rotation? There are two general approaches to this problem, one relying on the information in retinal flow and the other on extraretinal signals about eye and head rotation.

2.12.3.4 Retinal Flow Theories

It has been shown formally that the retinal flow pattern for a 3D scene contains sufficient information to recover the translational heading during rotation. This is possible in principle because a rotation simply adds a constant to the flow field, leaving the motion parallax intact. There are roughly five classes of retinal flow theories, which will be briefly described: discrete, differential, subtractive, local motion parallax, and template models (see Hildreth, E. C. and Royden, C. S., 1998; Warren, W. H., 1998; Lappe, M. *et al.*, 1999 for reviews).

Initially, several discrete models proved that observer translation and rotation can be computed from the motions of a minimum number of points in two successive images (Prazdny, K., 1980; Longuet-Higgins, H. C., 1981; Tsai, R. Y. and Huang, T. S., 1981). At the same time, a class of differential models showed that self-motion and surface slant can be determined from spatial derivatives of the flow field

such as divergence, curl, and deformation, as well as lamellar motion (Koenderink, J. J. and van Doorn, A. J., 1975; Longuet-Higgins, H. C. and Prazdny, K., 1980; Koenderink, J. J. and van Doorn, A. J., 1981; Waxman, A. M. and Ullman, S., 1985). However, these theories rely on precise measurements of a few points and are highly vulnerable to noise, or assume surface smoothness, casting doubt on their biological plausibility (see also Kappers, A. M. L. *et al.*, 1996).

A third class of theories first estimates the rotational component from the lamellar flow, and then subtracts it from the flow pattern to determine the translational component (Perrone, J. A., 1992). Koenderink J. J. (1986) noted that observer rotation during translation can be estimated by independently integrating the global flow about three orthogonal axes, and there is evidence for such a system in the rabbit (Simpson, J. I. *et al.*, 1981).

A complementary class of theories determines the translational component from local motion parallax, also known as differential motion (Longuet-Higgins, H. C. and Prazdny, K., 1980; Rieger, J. H. and Lawton, D. T., 1985; Lappe, M. and Rauschecker, J. P., 1993; Cutting, J. E., 1996; Royden, C. S. 1997). Differential motion is due to depth differences within a local neighborhood in the flow field and can be represented by a difference vector. Remarkably, the set of difference vectors once again forms a radial pattern centered on the heading and is invariant to rotation. The rotation problem can thus be solved quite elegantly if there is sufficient 3D structure in the scene.

Finally, a fifth class is based on templates for the set of flow patterns generated by possible combinations of observer translation and rotation (Perrone, J. A. and Stone, L. S., 1994; Beintema, J. A. and van den Berg, A. V., 1998; Perrone, J. A. and Stone, L. S., 1998). Each such template is selective for a complex motion pattern, rather than for an elementary flow component. Due to depth variation in the environment, however, the space of possible flow patterns is very large and must be constrained, for example, by assuming fixation of a point attached to the scene. These analyses demonstrate that it is theoretically possible to determine the observer's translation and rotation from the retinal flow pattern alone.

2.12.3.5 Extraretinal Theories

In contrast, the extraretinal approach proposes that efferent or proprioceptive signals about the rotational velocity of the eye and head are used to estimate the observer's rotation (Royden, C. S. *et al.*, 1994; Banks, M. S. *et al.*, 1996); interestingly, vestibular signals seem not to play a role (Crowell, J. A. *et al.*, 1998). In principle, the rotational component can then be subtracted from the retinal flow pattern in order to determine the instantaneous translational heading.

One possible implementation uses extraretinal velocity signals to subtract the rotational component at the level of MSTd, thereby shifting the preferred focus of expansion within the retinal receptive field. This implies head-centric expansion cells in MSTd that fully compensate for eye rotation. A related model realizes a least-squares solution to the rotation problem in the connection weights from MT to MSTd, augmented by extraretinal signals that modulate MSTd responses (Lappe, M., 1998). The model implies sigmoidal tuning curves and a population code for heading at the level of MSTd. Alternatively, MSTd cells might serve as templates for combinations of radial and lamellar flow, with extraretinal velocity signals modulating their response gain to create a heading map in a separate neural layer (Beintema, J. A. and van den Berg, A. V., 1998). This implies the existence of gain fields and head-centric expansion cells elsewhere in the dorsal pathway. A fourth possibility is a recurrent basis function network, with separate input layers that code oculocentric flow signals, head-centric vestibular signals, and extraretinal eye position signals, which are recurrently connected to a multisensory layer such as MSTd (Pouget, A. *et al.*, 2002; Fetsch, C. R. *et al.*, 2007). This model implies gain fields and a continuum of intermediate reference frames in MSTd, without convergence on common head-centric units.

2.12.3.6 Perception of Heading During Rotation

The empirical question at hand is whether humans can in fact perceive their instantaneous heading during an eye rotation on the basis of retinal flow alone, or whether extraretinal signals are necessary. The evidence, though still controversial, points to the conclusion that the visual system exploits both types of solutions.

2.12.3.7 Simulated Rotation

The rotation problem has been investigated using displays that simulate the retinal flow corresponding to a pursuit rotation, while the eye is actually

stationary (see Figure 2(c)); any extraretinal signal thus indicates zero rotation. Initially, Warren W. H. and Hannon D. J. (1988; 1990) reported heading thresholds better than 1.5° during both simulated and real eye rotation (for rotation rates $<1° s^{-1}$), as long as there was 3D structure in the scene, consistent with retinal flow theories based on motion parallax. With a frontal plane of dots, on the other hand (Figure 3), heading judgments were only accurate during real eye movements, consistent with extraretinal theories. Yet Grigo A. and Lappe M. (1999) reported accurate judgments during simulated rotation with a larger field of view, presumably due to global motion parallax from the periphery (Grigo, A. and Lappe, M., 1999). Subsequent research also supported some version of a retinal flow theory (Cutting, J. E. *et al.*, 1992; van den Berg, A. V. 1993; 1996; Stone, L. S. and Perrone, J. A., 1997; Wang, R. F. and Cutting, J. E., 1999).

However, when Banks, M. S. and his colleagues (Royden, C. S. *et al.*, 1992; 1994; Banks, M. S. *et al.*, 1996) tested higher rotation rates ($1–5 s^{-1}$), they found large heading errors of up to 15° in the simulated rotation condition, contrary to retinal flow theories. Whether the visual system can determine the direction of heading from retinal flow was thus cast into doubt.

2.12.3.8 The Path of Self-Motion

There is, however, a known ambiguity in the retinal flow: the same instantaneous velocity field can be produced by translation on a straight path plus a rotation, or by travel on a circular path (Figure 4). The retinal velocity field by itself is thus insufficient to distinguish straight and curved paths of self-motion, which is known as the path ambiguity.

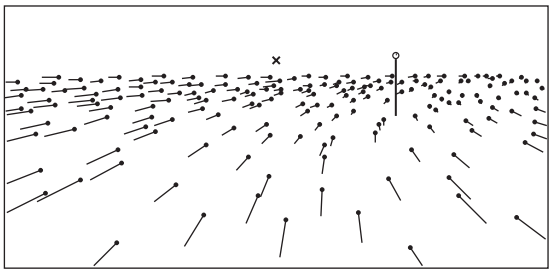

Figure 4 The path ambiguity. The same retinal velocity field can be produced by combined translation toward X while rotating about a vertical axis to track O, or by travel on a circular path to the right. Reproduced from Li, L. and Warren, W. H. 2000. Perception of heading during rotation: Sufficiency of dense motion parallax and reference objects. Vis. Res. 40, 3873, copyright 2000 by Elsevier Ltd.

(Theoretically, the ambiguity can be resolved by considering accelerative components of the flow or element trajectories over time, but the evidence suggests that the visual system is not sufficiently sensitive to these properties (Warren, W. H. *et al.*, 1991a; Ehrlich, S. M. *et al.*, 1998; Paolini, M. *et al.*, 2000).) Although the simulated rotation paradigm was intended to assess the perception of instantaneous heading (the tangent to the path at any moment), participants often reported seeing a curved path of self-motion, and their heading errors were consistent with this report (Royden, C. S., 1994). It thus appears that errors during simulated rotation were likely due to the path ambiguity, together with a tendency to judge the path of self-motion instead of the instantaneous heading, rather than evidence of the visual system's inability to decompose translation and rotation.

If the retinal flow is ambiguous, how might the visual system determine the path of self-motion? On an extraretinal approach (Banks, M. S. *et al.*, 1996), velocity signals can be used to subtract eye and head rotation from the retinal flow field; if the residual flow pattern has a rotational component, it is attributed to a curved path. However, this approach assumes accurate extraretinal signals, whereas their gain is believed to be significantly less than one (Wertheim, A. H., 1987). Moreover, the residual flow pattern may still need to be decomposed into translational and rotational components in order to estimate the curvature of that path (Ehrlich, S. M. *et al.*, 1998). On the other hand, once the path ambiguity is resolved, it is possible that the current path may be determined directly from the curved optic flow pattern (Lee, D. N. and Lishman, R., 1977; Warren, W. H. *et al.*, 1991b; Kim, N.-G. and Turvey, M. T., 1998).

Alternatively, the path ambiguity might be resolved by determining the object-relative heading, that is, heading, with respect to reference objects in the environment. (Li, L. and Warren, W. H., 2000). Specifically, if the instantaneous heading remains fixed relative to objects in the scene over time, then the observer is on a straight path, whereas if the heading drifts over reference objects, then the observer is on a curved path, and rate of drift corresponds to path curvature. Most previous research used sparse random-dot displays without reference objects that could be tracked over time. But when one or more distinct objects are added to a display containing textured surfaces, path errors remain below 4° (at $7° s^{-1}$) (Cutting, J. E. *et al.*, 1997; Li, L. and Warren,

W. H., 2000). This is also the case for active steering to a target during simulated rotation (Li, L. and Warren, W. H., 2002). Thus, with distinct reference objects and motion parallax from textured surfaces, the retinal flow solution tends to dominate the extraretinal solution.

Nevertheless, simulated rotation is a cue conflict condition, and hence features of the display or task can bias the observer toward one path or the other. Extraretinal signals indicate that the eye is not rotating, so the retinal flow pattern indicates the observer is on a curved path; yet the object-relative heading remains fixed in the scene, indicating that the observer must be on a straight path. Consistent with this analysis, when participants are told they are traveling on a straight path, errors remain below 4° (at 5° s^{-1}), whereas when they are told they are on a curved path, errors rise to 12° (Li, L. and Warren, W. H., 2004). Thus, the visual system has the capacity to recover observer translation from the retinal flow alone.

In sum, results from the simulated rotation paradigm indicate that both extraretinal and retinal flow solutions contribute to the perception of self-motion.

2.12.3.9 The Optic Flow Illusion

A second paradigm that bears on the decomposition of retinal flow is known as the optic flow illusion (Duffy, C. J. and Wurtz, R. H., 1993). When a transparent plane of laterally moving dots is superimposed on a plane of radially moving dots (Figure 5), the perceived location of the focus of expansion shifts in the direction of the lateral motion. This phenomenon suggests that the visual system uses the global lamellar flow to estimate eye rotation and compensates by shifting the perceived focus of expansion in the opposite direction (Duffy, C. J. and Wurtz, R. H., 1993; Lappe, M. and Rauschecker, J. P., 1995; Pack, C. and Mingolla, E., 1998).

However, the illusion can also be explained by motion-opponent operators that extract the local differential motion between the lamellar and radial flow patterns (Royden, C. S. and Conti, D. M., 2003). Such operators could be the basis for recovering heading from local motion parallax (Royden, C. S., 1997), and also account for biases in perceived heading induced by a moving object in the scene (Warren, W. H. and Saunders, J. A., 1995; Royden, C. S. and Hildreth, E. C., 1996; Royden, C. S., 2002). When local parallax is eliminated by presenting nonoverlapping flow patterns, the focus of expansion shifts only 17% as

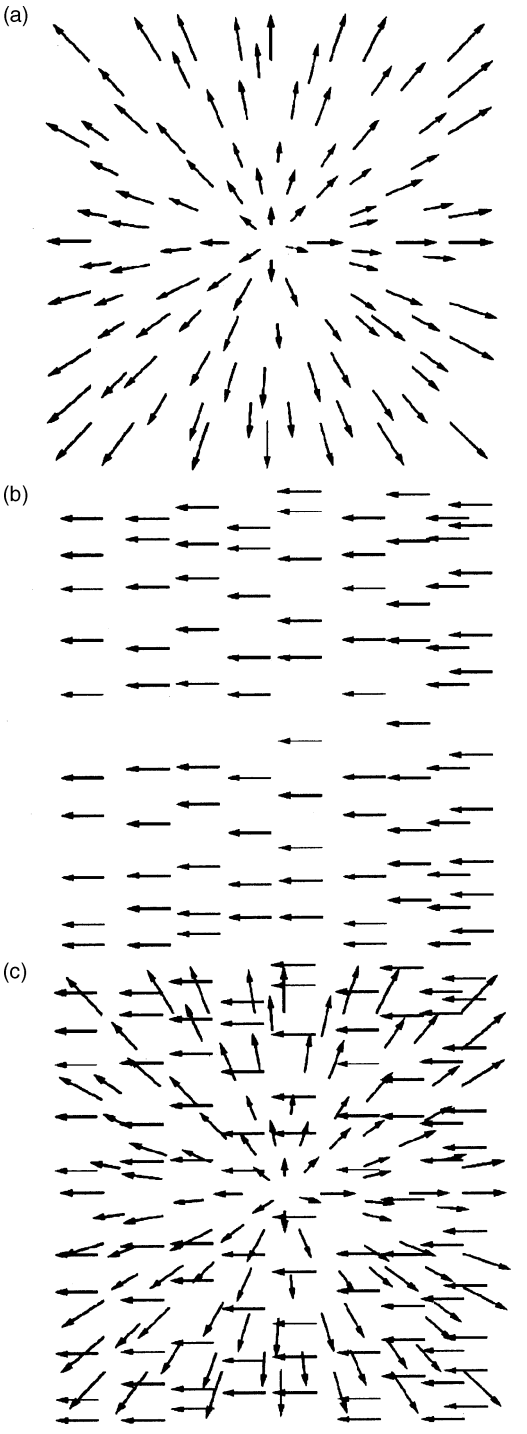

Figure 5 The optic flow illusion. (a) Radial flow pattern with a focus of expansion for one plane of dots. (b) Lamellar flow pattern to the left for second plane of dots. (c) Superimposed radial and lamellar flow patterns, which yield a perceived focus of expansion shifted to the left. Reproduced from Royden, C. S. and Conti, D. M. 2003. A model using MT-like motion-opponent operators explains an illusory transformation in the optic flow field. Vis. Res. 43, 2811, copyright 2003 by Elsevier.

far, but nonetheless a residual illusion persists (Duijnhouwer, J. *et al.*, 2006). It thus appears that both local motion parallax and global lamellar mechanisms are involved in decomposing the retinal flow. The lamellar motion might be extracted by large-field lamellar cells or by motion-opponent units with large surrounds.

2.12.3.10 Extraretinal Signals

The simulated rotation paradigm demonstrated that extraretinal signals contribute to the estimate of observer rotation. But work by Crowell J. A. and Anderson R. A. (2001) indicates that they do so in a particular way. When the retinal flow corresponds to a 3D scene (e.g., contains motion parallax), the rotational component is determined solely from the lamellar flow. Extraretinal signals merely indicate whether or not the eye is moving and serve to gate the interpretation of the lamellar flow as either being due to an eye rotation or to a curved path of self-motion. When the retinal flow does not contain motion parallax, observer rotation is determined from extraretinal signals, but is underestimated by nearly 50%. This implies that full pursuit compensation must also depend on the lamellar flow.

Moreover, extraretinal signals only begin to play a role 500 ms after the onset of flow, prior to which heading judgments are based solely on the retinal flow (Grigo, A. and Lappe, M., 1999). Given that fixation duration is normally 300–500 ms, this implies that ordinarily the visual system determines heading primarily from retinal flow.

2.12.4 Toward an Integrated View

2.12.4.1 Functional Level

The picture of self-motion perception that emerges from the psychophysical literature looks something like the following. First, observer translation is determined from motion parallax in the retinal flow field, which depends on 3D structure in the scene. The visual system appears to extract both local differential motion and global motion parallax, and this information seems sufficient to recover the instantaneous direction of heading.

Second, observer rotation is determined from the common lamellar motion in the retinal flow. The visual system appears to extract large-field lamellar flow that corresponds to eye rotation. This rotation estimate is subtracted from the retinal flow to contribute to the recovery of the translational component, as evidenced by the residual optic flow illusion.

Third, extraretinal signals similarly contribute to the recovery of observer translation, but in a limited way. When the retinal flow contains motion parallax, the rotational component is determined from lamellar flow, and extraretinal signals merely specify whether it should be attributed to eye rotation or a curved path. In the absence of motion parallax, the rotational component is estimated from extraretinal signals, but with low gain and only after 500 ms.

Finally, the path of self-motion appears to be based on the object-relative heading over time. A heading direction that is fixed in the scene specifies a straight path, whereas a heading that shifts with respect to environmental objects specifies a curved path.

2.12.4.2 Neural Level

The neural support for these functions remains contested, given that evidence can be found for competing theories. Consistent with local motion parallax theories, a majority of cells in area MT possess bilateral motion-opponent receptive fields (Allman, J. *et al.*, 1985; Xiao, D.-K. *et al.*, 1997) and project to MSTd. Expansion cells in MSTd could detect the radial pattern of difference vectors, and their response is enhanced when motion parallax is added to a radial flow display (Upadhyay, U. D. *et al.*, 2000). On the other hand, consistent with template theories, many MSTd cells respond to combinations of radial, rotary, and/or lamellar flow rather than constituting a simple heading map.

Extraretinal theories gain support from the finding that the preferred focus of expansion in most MSTd cells shifts within the retinal receptive field during a pursuit eye movement, partially compensating for the pursuit (Bradley, D. C. *et al.*, 1996; Shenoy, K. V. *et al.*, 1999; 2002; Lee, B. *et al.*, 2007). Such findings appear to be consistent with a heading map in MSTd. However, the shifts undercompensate for pursuit, although full compensation might occur with motion parallax in the display. Nevertheless, the population response seems to exhibit full pursuit compensation (Page, W. K. and Duffy, C. J., 1999), consistent with Lappe M.'s (1998) model. Alternatively, these partial shifts can also be interpreted as evidence of intermediate oculocentric and head-centric reference frames in MSTd, without convergence on head-centric units, consistent with a recurrent basis function network (Fetsch, C. R. *et al.*, 2007).

But recently, head-centric expansion cells have been identified in primate area VIP that exhibit full pursuit compensation with motion parallax in the display (Zhang, T. *et al*., 2004). This is consistent both with an extraretinal contribution and with determining rotation from lamellar flow in 3D displays. Such a VIP heading map is expected from the gain field model of pursuit compensation (Beintema, J. A. and van den Berg, A. V., 1998; van den Berg, A. V. and Beintema, J. A., 2000), and gain modulation of flow responses has been observed in MSTd and area 7a (Bremmer, S. *et al*., 1997; Read, H. L. and Siegel, R. M., 1997; Shenoy, K. V. *et al*., 1999).

Finally, neurons in area STPa respond to both optic flow and object boundaries in their receptive fields (Anderson, K. C. and Siegel, R. M., 1999). This suggests a possible site for the detection of object-relative heading.

2.12.4.3 Conclusion

In sum, current evidence indicates that the visual system exploits redundant information for robust perception of self-motion. Translational heading is determined from local and global motion parallax in the retinal flow pattern, whereas observer rotation is determined from lamellar motion and extraretinal signals and contributes to the estimate of instantaneous translation. The path of self-motion may be determined from the heading relative to environmental objects over time. These functions are carried out in a distributed dorsal network that integrates information in a head-centric heading map. Precisely how they are implemented across multiple cortical areas is a matter of ongoing investigation.

Glossary

biological motion Here, we use this term to refer to general motion of an animal or a human as compared to non-animate object motion. The usage of this term, however, varies in the literature. Some authors use it only in connection with the perception of point-light displays.

point-light displays An animation which shows only a number of small dots moving as if attached to the major joints or other parts of the body of a human or animal. Point-light displays convey a vivid percept of a moving figure and are a striking demonstration of the visual systems ability of perceptual organization.

superior temporal sulcus (STS) A prominent sulcus in the upper part of the temporal lobe of the primate brain.

double dissociation A double dissociation between two functions A and B exists when function A is not required for function B, and function B is not required for function A. The concept of a double dissociation is central to neuropsychological methodology.

periventricular leukomalacia (PVL) PVL occurs in fetuses and newborns and is particularly frequent in prematurely born neonates. It is caused by a lack of oxygen or blood flow to the periventricular area of the brain, which results in the death or loss of white matter brain tissue.

Down syndrome Down syndrome (or trisomy 21) is a genetic disorder caused by the presence of an extra instance of the 21st chromosome. The condition is characterized by a combination of differences in body structure and impaired cognitive disabilities.

brain imaging This term is used for a number of methods that allow researchers to watch the awake, functioning brain at work by imaging areas that are more active during a certain task than others. Among the most common methods are positron emission tomography (PET) and functional magnetic resonance imaging (fMRI).

A little more than 30 years ago, the Swedish psychologist Johansson G. (1973; 1976) fascinated the vision science community with an arresting demonstration of the organizational efficiency of the human visual system: he attached small light bulbs to the major joints of a human figure dressed entirely in black. Filming the movement of that figure created a highly reduced display that consisted only of a small number of white dots moving against a black background. Yet, it created the vivid and immediate percept of a human figure in action. Only 10 dots and 150 ms of display time were sufficient for a human observer to perceptually organize the dots into a fully coherent, articulated shape of a human figure, implicating the involvement of a highly specialized perceptual process. Today, we call Johansson's phenomenon biological motion perception, and the point-light displays he first used to demonstrate it have become recognized as a very effective research tool for studying the mechanisms upon which it is based. A demonstration of point-light displays and their potential to convey information about a walking person can be found at the website of The Bio Motion Lab.

The functional significance of this fascinating phenomenon lies in the vitally important ability to detect and to adequately interpret the movements of another animal. The other animal might be a predator, potential prey, or of one's own kind. If the latter is the case, it might be a potential mate, a rival, or

Box 1

Point-light displays in current research typically depict the motion of the main joints of a human body in terms of small dots. Johansson G. (1973) had already started to replace actively light-emitting light bulbs with patches of passively reflecting material. Particularly with the advent of broad availability of video technology, it became easy to process the recorded material such that only the reflections would be visible as bright dots on a uniformly black background. Today, many laboratories employ three-dimensional (3D) motion capture technology to create stimuli for biological motion research (Figure 1). Such systems provide the digitized 3D trajectories of small markers that are attached to an actor's body. The data can in turn be rendered into typical point-light displays. In contrast to older film and video technology, the enormous advantage of motion capture technology lies in its access to the motion data themselves, rather than just the final visual display. The same motion data can now be displayed from any viewpoint and individual trajectories can be displaced, inverted, or otherwise manipulated before turning them into a stimulus. Dots can be connected to create stick figures or they can be used to animate 3D computer graphics characters. The time series of marker locations can also be used as input for biomechanical models designed to retrieve the true joint locations and other anatomical landmarks inside the body from the markers attached to its surface, as well as moments and forces acting on the body. Finally, they also provide valuable input for computational models of human biological motion processing.

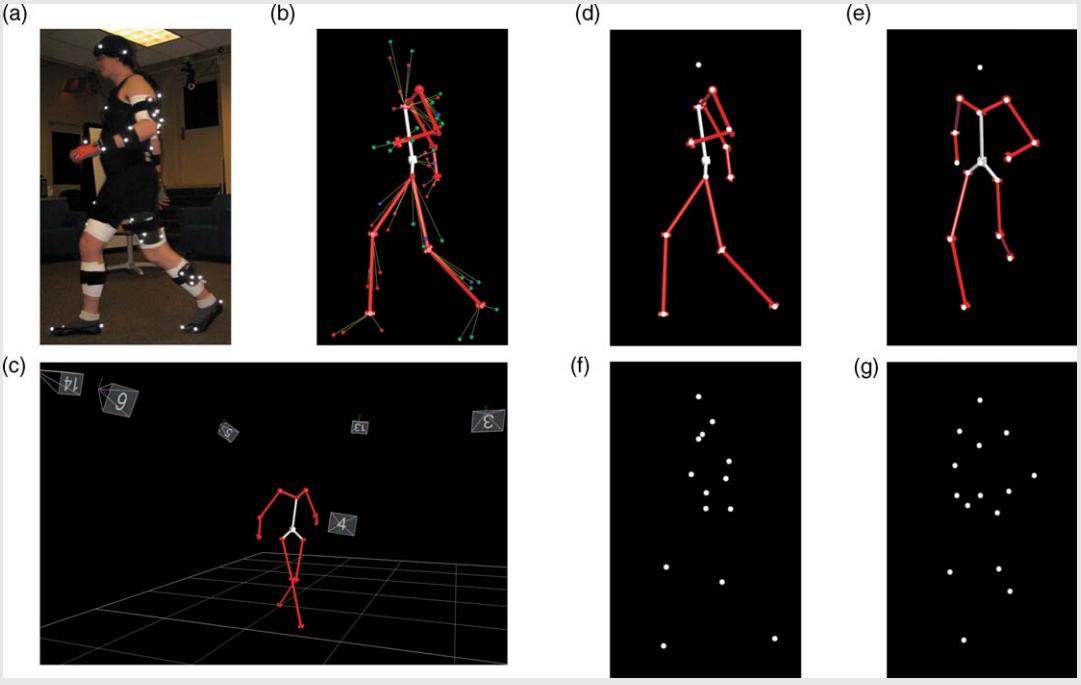

Figure 1 For optical motion capture, a person is attached with a number of retroreflective markers to his body (a). An array of high-speed video cameras tracks the markers and reconstructs their trajectories in three-dimensional space (c). These marker trajectories are then used as input for a biomechanical model (b) that computes the movements of anatomical landmarks, such as the major joints of the body (d). These are then displayed in terms of point-light displays (e). Because the underlying biomechanical model is inherently three dimensional, similar displays can be created from other viewpoints (f and g).

maybe a particular individual that we depend on, for instance, a parent or an offspring. Visual motion plays a major role in identifying another living creature and can inform the observer about its actions and intentions. Humans are highly social animals. Not surprisingly, this is reflected in many specializations of our sensory systems, such as the ability to comprehend speech, to recognize faces, and – the topic of this chapter – to retrieve information from the way a person moves.

Signatures contained in biological motion patterns identify the agent as an animal or human figure (Mather, G. and West, S., 1993) and reveal its actions (Dittrich, W. H., 1993). They are sufficient to

recognize a familiar person (Cutting, J. E. and Kozlowski, L. T., 1977; Troje, N. F. *et al.*, 2005; Westhoff, C. and Troje, N. F., 2007) and to attribute socially relevant attributes such as sex, age, mental states, actions, and intentions to unfamiliar individuals (Barclay, C. D. *et al.*, 1978; Mather, G. and Murdoch, L., 1994; Runeson, S., 1994; Dittrich, W. H. *et al.*, 1996; Blakemore, S. J. and Decety, J., 2001; Pollick, F. E. *et al.*, 2001; Troje, N. F., 2002a; 2002b). Research into the cues that convey this information unveils a rich composition of configural, anthropometric features, on the one hand, and kinematic features such as speed and spectral composition of the point-light trajectories, on the other hand (Pollick, F. E. *et al.*, 2001; Troje, N. F., *et al.*, 2005; Westhoff, C. and Troje, N. F., 2007). If pit against one another, the information provided by kinematic features clearly dominates the role of static features (Mather, G. and Murdoch, L., 1994; Troje, N. F., 2002a).

The ability to perceive biological motion arises early in life. Four-month-old infants stare at human motion sequences for longer durations than they will at the same number of dots undergoing random motions (Fox, R. and McDaniel, C., 1982; Bertenthal, B., 1993), and event-related potential (ERP) studies imply that the brain areas involved are similar to the ones found in adults (Jokisch, D. *et al.*, 2005; Reid, V. M. *et al.*, 2006). On the other hand, however, children show a number of fundamental differences in the way they perceive biological motion and keep improving their ability to retrieve the shape of a moving body until they reach adult levels of performance at about the age of 5 (Pavlova, M. *et al.*, 2001).

In the adult brain, multiple areas are involved in biological motion processing (for comprehensive reviews, see Allison, T. *et al.*, 2000; Puce, A. and Perrett, D. I., 2003). Recording from single cells in macaque cortex, Oram M. W. and Perrett D. I. (1994) first identified structures in the upper bank of the superior temporal sulcus (STS) as selectively responsive to human form and motion. A number of more recent brain imaging studies corroborate this finding and show that the posterior part of STS (STSp) is particularly active when looking at point-light displays of an upright human walker (Bonda, E. *et al.*, 1996; Grossman, E. D. *et al.*, 2000; Grossman, E. D. and Blake, R., 2002; Grossman, E. D. *et al.*, 2004; Peuskens, H. *et al.*, 2005). While STSp is clearly responsive to biological motion, it is not clear how specific this area is. Stimuli such as faces (Grossman, E. D. and Blake, R., 2002), speech (Beauchamp, M. S., 2005), the sound of footsteps (Bidet-Caulet, A. *et al.*, 2005), and visual motion confined to specific limbs, the eyes, or mouth (Grezes, J. *et al.*, 1998; Puce, A. *et al.*, 1998) also result in STSp activation. Besides STSp, other areas have been identified that are responsive to biological motion. They involve the ventral surface of the temporal lobe (Vaina, L. M. *et al.*, 2001), the fusiform gyrus (Beauchamp, M. S. *et al.*, 2002), and the fusiform face area (Grossman, E. D. and Blake, R., 2002; Peelen, M. V. and Downing, P. E., 2005). For all these areas, it is rather unclear if they respond specifically to human motion or if they are triggered generally by biological motion. Only very few imaging studies have contrasted representations of humans versus nonhumans, and none of these has used standard biological motion point-light displays (Downing, P. E. *et al.*, 2001; Buccino, G. *et al.*, 2004). More research is required to characterize and understand the neuronal circuits involved in the perception of biological motion.

Given the complexity and sophistication of biological motion perception, it is not surprising that it is susceptible to failure. Case studies with brain-lesioned patients demonstrate a double dissociation between general motion perception and the ability to see and interpret biological motion (Vaina, L. M. *et al.*, 1990; McLeod, P. *et al.*, 1996). Specific deficits in the ability to perceive and adequately interpret biological motion patterns have also been described in the context of a number of different disorders. Autistic children have been demonstrated to show deficits in biological motion perception (Blake, R. *et al.*, 2003; Dakin, S. and Frith, U., 2005), which is consistent with the finding that they also show STS abnormalities (Waiter, G. D. *et al.*, 2004). Patients suffering from periventricular leukomalacia (PVL), which is often present in children born prematurely, have been described to be compromised in their ability to perceive biological motion (Pavlova, M. *et al.*, 2003; 2005; 2006a; 2006b). Impairments in biological motion perception have also been described in schizophrenic patients (Kim, J. *et al.*, 2005) and in children with Down syndrome (Virji-Babul, N. *et al.*, 2006).

In many respects, the information contained in biological motion and our ability to exploit it resembles the phenomenology of face recognition (see Chapter Face Recognition). For instance, both visual domains are highly susceptible to a pronounced inversion effect: if a point-light stimulus (or a face) is turned upside down, perception is strongly impaired (Sumi, S., 1984; Pavlova, M. and Sokolov, A., 2000). For faces, there is convincing evidence that the inversion effect is caused by an impairment of mechanisms

responsible for assessing the details of the spatial configuration of facial features (Farah, M. J. *et al.*, 1995; Maurer, D. *et al.*, 2002), and the same has been implied to be the case for biological motion (e.g., Proffitt, D. R. and Bertenthal, B. I., 1990; Dittrich, W. H., 1993; Reed, C. L. *et al.*, 2003; Troje, N. F., 2003).

A number of debates have arisen concerning the mechanisms that serve the complex visual abilities involved with biological motion perception. One of them concerns the question to what extent biological motion perception is driven by global, conceptual information processing and to what extent it is determined by local, low-level motion processing. While some authors think that local motion is sufficient (e.g., Mather, G. *et al.*, 1992), others clearly demonstrate global effects (e.g., Neri, P. *et al.*, 1998). Another dispute that is connected to the question about the role of local versus global information (Thornton, I. M. *et al.*, 1998) concerns the contributions of attentional mechanisms (Cavanagh, P. *et al.*, 2001; Thornton, I. M. *et al.*, 2002) and the role of learning (Grossman, E. D. *et al.*, 2004; Hiris, E. *et al.*, 2005; Jastorff, J. *et al.*, 2006). Finally, there are seemingly contradictory findings about how well biological motion can be processed in the visual periphery (Thompson, B. *et al.*, in press; Ikeda, H. *et al.*, 2005). Here, we want to argue that these controversies can be resolved only if we acknowledge that biological motion is not a single phenomenon but consists of a number of different aspects that have to be distinguished carefully – both conceptually and experimentally. Typical paradigms used in biological motion research such as detecting a point-light walker in a mask or deriving the direction into which the walker is facing might address very different processing stages and are therefore not interchangeable but may address very different processing stages.

The majority of biological motion research focuses on the impressive ability to organize the individual dots of a point-light display into the coherent structure of a human body. Here, we will refer to this as the structure-from-motion aspect of biological motion perception. In general, such a focus is not explicitly intended but results from a standard task widely used in biological motion research: the detection of a point-light walker that is masked by superimposing it with multiple scrambled walkers. Scrambled walkers are derived from veridical, coherent point-light walkers by adding a random but constant offset to the location of the single trajectories. This manipulation disrupts the structure of the display but leaves the local motion of the individual dots intact. The only difference between a display that consists only of a mask of scrambled walkers and the one that embeds a coherent walker in this mask is the presence of the coherent structure of the single walker. A similar focus also characterizes large parts of the brain imaging literature. Here, brain activity in response to intact biological motion is often contrasted with responses to scrambled motion – a contrast that once again reduces biological motion perception to its structure-from-motion aspect.

In a recent study by Troje N. F. and Westhoff C. (2006), it was shown that scrambled biological motion of humans and animals, even though devoid of any structural information, still carries information about the direction in which a walker was facing (Figure 2). Interestingly, observers can exploit this information only if the stimulus is presented upright. Since the locations of the individual dot trajectories are random in a scrambled biological motion display, the information about the direction as well as the corresponding inversion effect must be contained in local dot trajectories. In fact, it could be shown that the critical information is carried by the motion of a human's or animal's feet. The dependence on orientation is hypothesized to be due to inherent expectations about the direction of gravitational acceleration, an assumption corroborated by earlier findings on the role of heuristics about gravity in the perception of biological motion (Runeson, S., 1994; Jokisch, D. and Troje, N. F., 2003; Shipley, T. F., 2003) and nonanimate motion (Pittenger, J. B., 1985; Watson, J. S. *et al.*, 1992). Troje N. F. and Westhoff C. (2006) suggest that the sensitivity to the dynamics of the feet reflects its potential role as a visual invariant for the nonspecific detection of an animal in the visual environment.

I want to conclude this chapter by pointing out that biological motion perception is not just a single phenomenon. In order to fully understand and appreciate its rich and fascinating phenomenology, we have to distinguish between a number of different processing levels:

1. *Life detection.* Troje N. F. and Westhoff C. (2006) identified the ballistic movements of the limps of a terrestrial animal to provide an invariant that our visual system uses to spot an animal in the visual environment independent of its particular shape. The cue seems to work well not only for foveal vision but also in the visual periphery (Thompson, B. *et al.*, in press) and probably directs attention to an event of potentially vital significance. The

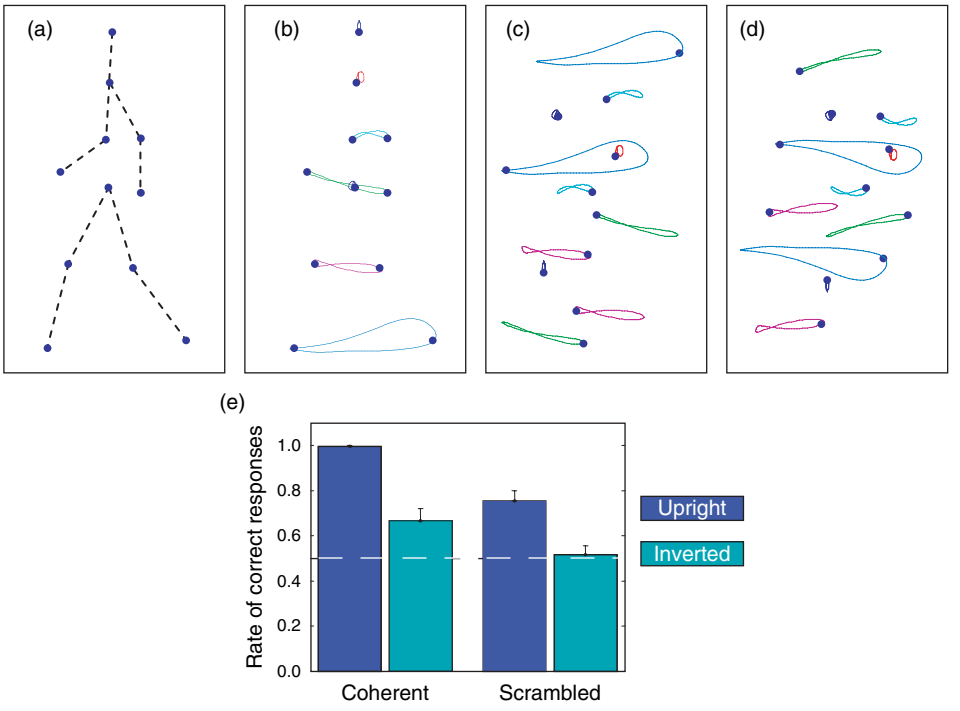

Figure 2 Scrambled biological motion is derived from normal, coherent biological motion (a and b) by randomly offsetting the trajectories of the individual dots (c). This disrupts the structure of the human figure. Yet, if asked in which direction 'this odd creature' is facing, observers are still quite accurate. Only if the scrambled point-light display is turned upside down (d), performance drops to chance level (e). The dashed lines that show the articulation of the individual dots (a) and the solid lines that illustrate their trajectories (b, c, and d) are not shown in the experiment. Visit http://www.biomotionlab.ca/Demos/scrambled.html for an interactive animation that demonstrates the stimuli. For experimental details, see Troje N. F. and Westhoff C. (2006).

underlying visual filter mechanism is expected to be evolutionary old and shared by other animals as well. Behavioral experiments on visually naive, newly hatched chicks suggest that they use the same cue to identify the object of filial imprinting and they even show the same inversion effect (Vallortigara, G. *et al.*, 2005; Vallortigara, G. and Regolin, L., 2006).

2. *Structure-from-motion.* Once a living creature is detected, its movements can be used to perceptually organize it into a coherent, articulated body structure, resulting in 'basic level' (Rosch, E., 1988) agent recognition (e.g., is this a human, a cat, or a bird?). In contrast to the early 'life detection' stage, this mechanism does not work very well in the visual periphery (Ikeda, H. *et al.*, 2005), it probably requires attention (Cavanagh, P. *et al.*, 2001; Thornton, I. M. *et al.*, 2002), and it is susceptible to learning and individual experience (Jastorff, J. *et al.*, 2006). It is also subject to an inversion effect, which, however, is independent of the one operating on the 'life detection' mechanism and rather related to the orientation dependency of configural processing observed in face recognition. The relation between the two mechanisms for life detection and for structure-from-motion retrieval might be similar to the relation between two processes in the development of face recognition suggested by Morton J. and Johnson M. H. (1991). These authors suggested that an innate system guides attention to face-like patterns, while a second mechanism is responsible for learning about the detailed characteristics of faces required for individual face recognition.
3. *Action recognition.* On this level, structural and kinematic information is integrated into a system that classifies and categorizes the action. Efficient classification on this level is expected to be invariant to the particular agent, viewing conditions, and the style of the action. As yet, we know rather little about this processing level. More research is required to understand which features define a

particular action. Some interesting ideas may come from recent work on general event perception (e.g., Zacks, J. M., 2004). Given the ease with which the human visual system categorizes actions, the difficulty to experimentally and theoretically identify action-specific invariants is surprising – and probably related to the harsh contrast between human 'basic' level (Rosch, E., 1988) object classification and the lack of good computational models for it.

4. *Style recognition.* Once both agent and action are identified, pattern recognition at a 'subordinate' level (Rosch, E., 1988) helps retrieve further information about the details of both. For instance, once we know we are confronted with a human walker (let's say, rather than a hunting tiger), we are able to use motion as a source of information about individual identity, gender, age, emotional state, personality traits, and as a complex means for signaling and communications. Depending on the particular property, the results of initial data processing required to characterize and isolate diagnostic features might eventually feed into different neuronal circuits, and in that respect 'style recognition' might not be due to a single mechanism but to several. Yet, at least from a computational point of view, it is very likely that all of them share certain processing principles (Troje, N. F., 2002a; 2002b).

Adopting this multilevel view has important implications for understanding biological motion perception. It resolves many of the above-mentioned debates (local vs. global, role of attention and learning, foveal vs. peripheral vision) in a canonical way. Furthermore, it generates new hypotheses about the development of biological motion perception, both ontogenetically and evolutionarily. It also has implications concerning the role of impaired biological motion perception in disorders that affect social competence and the complex sensory basis of communicative behavior.

Before I finish this short review on biological motion perception, I want to point out that it is by no means comprehensive. Much more work has been done in all the areas that I tried to cover here. In addition, there are topics that I did not address at all. One of them refers to the large field of computational models for human motion recognition. Some of the models are explicitly biologically motivated, trying to incorporate information we have about the physiology of biological motion perception (e.g., Giese, M. A. and Poggio, T., 2003). On the other hand, there is a large body of work conducted in the fields of computer vision and machine learning that approaches biological motion perception as a pattern recognition problem. Another area that I did not even try to address given the limited scope of this chapter is the interesting question of understanding biological motion in the context of human interaction. Concepts such as simulation theory, common-coding theory (Prinz, W., 1997), the direct-matching hypothesis (Rizzolatti, G. *et al.*, 2001), and particularly the discovery of mirror neurons in the monkey brain (Gallese, V. *et al.*, 1996; Rizzolatti, G. *et al.*, 1996) provide an interesting basis for speculations about how the behavior between two interacting people becomes coupled and coordinated (Decety, J. and Grezes, J., 1999; Blakemore, S. J. and Decety, J., 2001). The perception of social contingency and the mechanisms through which it determines our own actions in social situations probably has to be considered a fifth level in the above proposed taxonomy of levels of biological motion perception.

Glossary

transparency The property of objects, surfaces, and media that allows for the transmission of light.
lightness The proportion of light reflected by a surface.
occlusion The interruption of the optical projection of a more distant object by a nearer object.
scission The decomposition of an image into multiple surfaces or causes along the same line of sight.
transmittance The proportion of light that passes through an object.

One of the great computational challenges in recovering scene structure from images arises from the fact that some surfaces in a scene are partially obscured by nearer surfaces or media. Both occluding and transparent surfaces interrupt the projection of more distant surfaces, and may be considered two ends of a continuum. Occluding surfaces completely obscure the surfaces that they occlude, whereas transparent surfaces only partially obscure the surfaces they overlay. The degree to which a transparent surface obscures an underlying surface depends on its transmittance (i.e., the proportion of light that it lets through of the underlying layer). Thus, when the transmittance is zero, the near surface is an opaque occluder; when it is greater than zero, some light of the underlying layer is transmitted. In order for the visual system to recover scene structure in contexts in which the transmittance of a near layer falls between zero and one, it must decompose the image into a layered representation that specifies the presence of multiple surfaces (or a surface and intervening media) along the same line of sight. This form of decomposition has been termed scission.

In addition to the relationship between transparency and occlusion, the physical transformations induced by transparent surfaces are intimately related to the physical transformations that are caused by changes in illumination. This suggests the possibility that the scission that underlies the perception of transparency may also underlie the separation of illumination from surface reflectance, and hence, the computation of surface lightness and/or color. Thus, the topic of transparency is intimately related to two apparently distinct domains: the computation of occlusion relationships and the computation of surface lightness. In this chapter, I will describe some recent evidence that reveals the intimate relationship between scission and the perception of surface opacity, lightness, and depth, and the impact this research has on theoretical frameworks in vision more broadly.

2.14.1 The Computation of Transparency

The topic of transparency emerged as a fundamental area of vision research with the seminal work of the Italian psychologist Metelli F. (1970; 1974a; 1974b). Metelli developed a model of transparency based on the physical setup he used to generate of transparent images – namely, a disk with a missing sector (episcotister) that rotated in front of a two-toned background (see Figure 1). Metelli derived a simple set of equations that described the relationship between the reflectance of the underlying background surfaces,

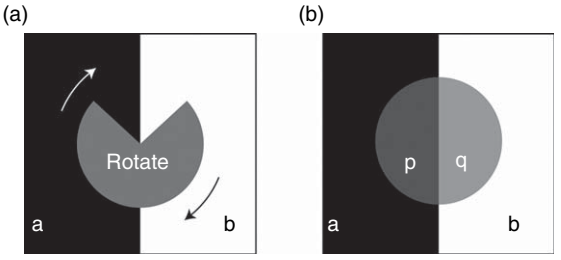

Figure 1 A schematic of Metelli's episcotister setup that served as the basis of his model of transparency. (a) An opaque disk with a missing sector subtending angle α is rotated over a two-toned background. When spun rapidly, it produces a percept similar to that depicted in (b). Note that the transparent surface appears to possess a particular opacity and color (here, an achromatic lightness).

the transmittance of the transparent filter (i.e., the size of the missing sector), and the reflectance of the transparent layer. Metelli argued that perceived transparency was well predicted by the physical constraints that must be satisfied to produce a transparent surface, and thus, embraced an inverse optics approach to modeling visual perception. In particular, Metelli used his episcotister display to derive a physical model for the transmittance (α) and reflectance (t) of the transparent surface, which was just a weighted sum of the contributions of the light transmitted from the underlying layer and that reflected by the episcotister:

$$p = \alpha a + (1-\alpha)t \quad [1]$$

$$q = \alpha b + (1-\alpha)t \quad [2]$$

where p is the region containing the transparent layer that overlaps background a; q is the region containing the transparent layer that overlaps background b; and α is the transmittance of the transparent layer (i.e., the proportion of the size of the holes in the episcotister). These equations can be solved to derive separate expressions for the transmittance and reflectance of the transparent surface:

$$\alpha = (p-q)/(a-b) \quad [3]$$

$$t = (aq-bp)/(a+q-b-p) \quad [4]$$

To make physical sense, α is restricted to be between 0 and 1, which imposes two basic constraints on the images that are consistent with transparency: the luminance difference between the regions of transparency $(p-q)$ must have the same sign as the luminance difference between the regions in plain view $(a-b)$ (to ensure that α is positive); and the magnitude of the luminance difference of the regions of transparency $(p-q)$ must be less than or equal to the luminance difference of the surface in plain view $(a-b)$; (to insure that the transmittance falls between 0 and 1). Perhaps the most salient restriction of the applicability of these equations is that they can only be used to describe transparent filters containing a uniform reflectance and transmittance. They make no predictions of displays containing unbalanced transparent filters or media, that is, forms of transparency that are not uniform in reflectance and/or transmittance. Note that Metelli's model is a purely generative model, that is, his equations described the (simplified) physics of his episcotister display. Thus, the issue of whether such equations could be used to predict when, whether, and how transparency was perceived is an issue that required psychological experimentation.

Nearly three decades of research into transparency perception seemed to provide compelling evidence that Metelli's model successfully predicted when transparency was and was not perceived (Metelli, F., 1974a; 1974b; 1985; Metelli, F. *et al.*, 1985; Gerbino, W. *et al.*, 1990; Kasrai, R. and Kingdom, F., 2001). However, we have recently argued that that this apparent success stems from the particular methodologies employed to assess his model. Although Metelli derived separate expressions for the transmittance and reflectance of a transparent surface, until recently, no experiments assessed whether these expressions accurately captured human perception of transparent surfaces. Rather, most experiments typically required observers to adjust (or otherwise judge) the luminance of a test patch in a display until it appeared to form a uniform transparent filter; they did not measure whether Metelli's equations could quantitatively predict the perceived transmittance and reflectance of a transparent filter.

To provide a more direct quantitative test of Metelli's model, we (Singh, M. and Anderson, B. L., 2002) recently performed a number of experiments to directly assess whether his equations correctly predicted the perception of transparency. In these experiments, observers were required to separately match the transmittance and reflectance of a transparent filter. Observers viewed displays containing a central sine wave grating surrounded by a higher contrast sine wave grating of the same frequency, orientation, and phase. To enhance the perception of transparency, binocular disparity was added to the edges of the central patch, giving rise to a clear

percept of a homogeneous transparent filter lying on top of a high-contrast grating. Metelli's model predicts that the perceived transmittance of a transparent filter should only depend on the ratio of luminance differences (i.e., the luminance range) of the regions of transparency to the regions in plain view (see eqn [3]). In one of our experiments, the luminance range of the region in plain view (the high-contrast grating) and the luminance difference of the region of transparency was held constant; only the mean luminance of the region of transparency was varied. Observers adjusted the luminance range of a matching pattern to match the perceived transmittance of the transparent filter with varying mean luminance values. In this experiment, the luminance range of the region of transparency and the region in plain view are constant, so Metelli's equations predict that the transmittance settings in this experiment should be independent of mean luminance. This was not at all what was observed experimentally. Rather, observer's matches are very strongly dependent on the mean luminance of the transparent region (see Figure 2). In particular, observers significantly underestimate the transmittance of light filters, and systematically overestimate the transmittance of dark filters.

The results of this experiment reveal that human observers are not simply inverting the physics of transparency to compute the properties of transparent surfaces. The theoretical importance of this finding should not be underestimated, as one of the main theoretical views of visual processing assumes that the visual system extracts the properties of the world by performing computations that invert the image formation process. These results on the perception of transparency provide a striking example where human observers have a very clear sense of a surface property (the transmittance of a transparent layer) that almost always generates the physically incorrect answer. Why, then, does the visual system err in this manner? What information is the visual system using to compute these properties that causes it to give such incorrect responses? One of the main problems with Metelli's model is that it assumes that

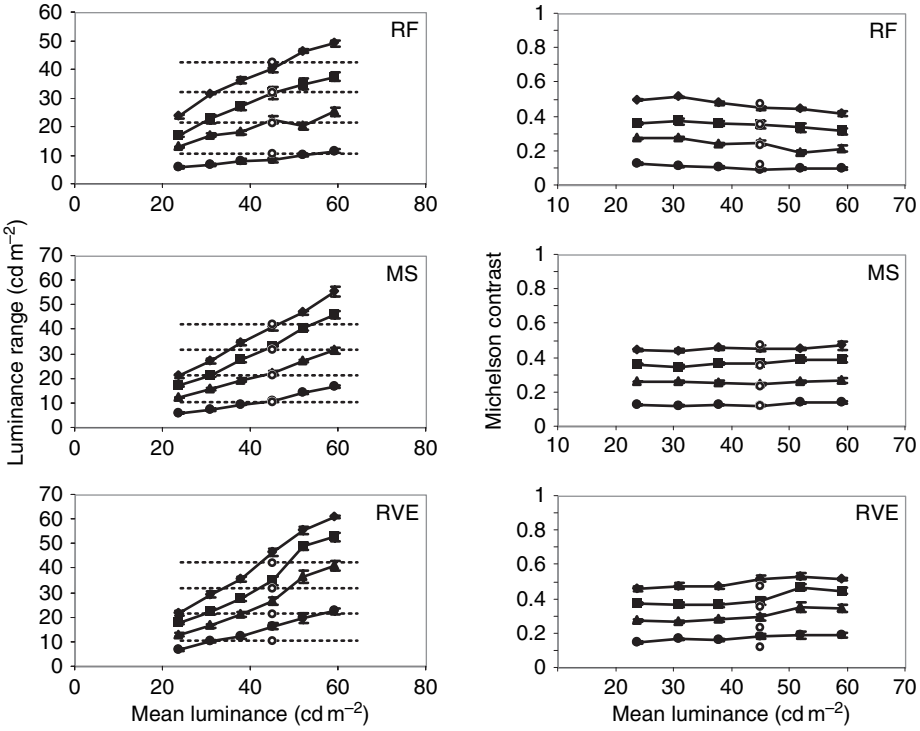

Figure 2 Results from the Singh M. and Anderson B. L. (2002) transmittance matching experiment for three observers (RF, RVE, and MS). Observers adjusted the perceived opacity of a matching pattern to the opacity of a target patch that varied in mean luminance. The open circles depict when the mean luminance of the target and match were identical; the dashed lines in the figure on the left correspond to the predictions of Metelli's model. The right-hand figure reveals that the data are independent of mean luminance when plotted in terms of Michelson contrast, showing that observers rely on contrast when matching the opacity of transparent filters.

transmittance is computed on the basis of the ratio of luminance differences between the regions of transparency and the regions in plain view. (Strictly speaking, Metelli's model is formulated on the basis of reflectance differences. However, Gerbino, W. *et al.* (1990) showed that Metelli's equations could be rewritten as difference in luminance values, and that the form of these equations were identical to eqns [1]–[4].) However, the earliest stages of cortex have little access to raw luminance values. Rather, the information about image structure seems to be largely transformed into a contrast code. Indeed, when the data from this experiment are plotted in terms of Michelson contrast, it becomes evident that the visual system uses contrast to scale the transmittance of a transparent surface, even though this yields the physically incorrect answer. In our sinusoidal displays, Michelson contrast provides a good measure of perceived contrast, so works well in accounting for perceived contrast in our displays. However, Michelson contrast fails to provide an adequate measure of contrast in more complex spatial patterns containing, for example, random patches of achromatic surfaces. Despite these shortcomings, recent work has shown that observer's transparency judgments can be well described by the perceived contrast of images (Robillotto, R. *et al.*, 2002; Robillotto, R. and Zaidi, Q., 2004), suggesting that transparency computations are indeed based on some measure of image contrast.

In sum, there is now clear evidence that the visual system uses the relative contrast of image regions to compute the opacity of transparent surfaces. In what follows, I will consider the implications that this discovery has had in understanding when the decomposition into a layered representation is initiated, and the consequences that this decomposition can have on not just the properties of the transparent surface, but the underlying surface as well.

2.14.2 Anchoring Perceived Transmittance

In addition to the quantitative failures of Metelli's model, it was also not easily generalized to a variety of naturally occurring forms of transparency. Metelli's model only described conditions of balanced transparency, that is, conditions where the transmittance and reflectance of the transparent layer is uniform. However, many naturally occurring forms of transparency – such as that induced by smoke and fog – are typically unbalanced, particularly in transmittance. Clearly, a more general framework is needed to understand the wide variety of ways that transparent surfaces and media can transform image structure. How does the visual system determine whether a scene is in plain view or viewed through a transparent layer or medium when the properties of the transparent layer vary continuously?

If image contrast is the currency through which the properties of transparent surfaces are computed, then any general theory of transparency perception will have to use image contrast as one of main ingredients in the computation of transparency. However, all natural scenes generate variations in image contrast, and the properties of the underlying surfaces are unknown. So how can the visual system determine whether a given image arose from a scene in plain view or a higher contrast scene viewed through a (contrast reducing) transparent layer? The image data is always consistent with both possibilities, so something is needed to understand how the visual system determines when transparency is and is not perceived. I have recently proposed that the visual system employs a transmittance anchoring principle to determine when transparency is (and is not) inferred (Anderson, B. L., 1999; 2003a). The intuitive content of this principle is that the visual system assumes the fewest surfaces necessary to account for the image data. More specifically, it states that the visual system treats the highest contrast region along surfaces and contours as transmittance anchors that are in plain view. All other contrast values along such contours and/or surfaces are compared to this anchor region, and decreases in contrast along surfaces are used to infer the presence of transparency. More specifically, this theory asserts that if there are reductions in contrast along surfaces or contours that are geometrically continuous, then scission is initiated and transparency is perceived. The magnitude of the contrast reduction is used to compute the transmittance of the overlying (transparent) layer (in proportion to this reduction; i.e., the greater the contrast reduction, the more opaque the transparent surface will appear). In the limit, where the contrast of the underlying surface goes to zero, the transmittance of the overlying surface goes to zero, and the near layer becomes an occluder. Note also that if a change in mean luminance occurs without a corresponding reduction in contrast, that such transformations are consistent with a change in illumination, and hence, would be correctly predicted to appear in plain view in both regions of the image.

Thus, the contrast relationships along surfaces and contours could be used to provide information about both transparent media and changes in illumination.

We have recently shown that this theory correctly predicts the perception of transparency in both balanced displays, as well as spatially inhomogeneous media (Anderson, B. L. *et al.*, 2006). In addition, we have shown that transmittance anchoring also has a temporal component: if the contrast of a texture is modulated in time, the highest contrast region in the spatiotemporal sequence is treated as a region in plain view, and the spatiotemporal reductions in contrast appear as the intrusion of transparent media. Thus, the transmittance anchoring principle appears to provide a foundation on which to predict when transparency is and is not perceived, and the perceived transmittance of the transparent layer.

2.14.3 Scission and the Perception of Lightness

The decomposition of an image region into multiple layers can also have a significant impact on perceived lightness. In the preceding, I have focused on how variations in image contrast can be used to determine whether transparent surfaces are present, and if so, how the opacity of the transparent layer is computed. However, when multiple surfaces are present along the same line of sight, the visual system must also compute properties of the underlying surface, such as its lightness. Given the close relationship between the physical transformations induced by transparent surfaces and the transformations induced by changes in illumination, there is good *a priori* reasons to suspect that a process of scission may play a critical role in the perception of surface lightness. Although a number of authors have suggested the possibility that scission may play a critical role in lightness perception (Anderson, B. L., 1997; Bergström, S. S., 1977; Gilchrist, A. L., 1977; 1979; Adelson, E. H., 1993), such authors have questioned whether an explicit decomposition actually underlies lightness perception. More recently, we have been developing a new paradigm that explicitly reveals the role that scission can play in the perception of surface lightness (Anderson, B. L., 1999; 2003a; 2003b; Anderson, B. L. and Winawer, J., 2005). Traditional lightness studies typically employ homogeneous targets to be judged and measure the effect different contexts have on their perceived lightness or brightness. In such paradigms, it can often be difficult to determine whether scission is occurring, and if so, whether it is playing any causal role in the perceived lightness of a figure. However, in the paradigm we have developed, if scission occurs, it is phenomenologically very explicit, and the effects it has on perceived lightness can be directly experienced.

To see the role that scission can play in lightness perception, consider the image depicted in Figure 3. This figure appears to contain white chess pieces viewed through dark smoke, and black chess pieces viewed through white fog. However, the image regions containing the chess pieces in the top and bottom of the image are actually absolutely identical; the only difference between the top and bottom images is the overall lightness of the surrounds. These images were carefully constructed to satisfy the constraints of transparency. In the top image, all of the boundaries separating the chess pieces from the surround are lighter inside the chess pieces than outside (so that the boundary separating the regions has the same contrast polarity), whereas the opposite polarity holds for the bottom figure. In addition to the shift in polarity between the top and bottom figure, there are also significant differences in the way the magnitude of contrast varies along the borders separating the chess pieces and their surrounds in the two images. Consider, for example, the king in the two images. In the top figure, the greatest

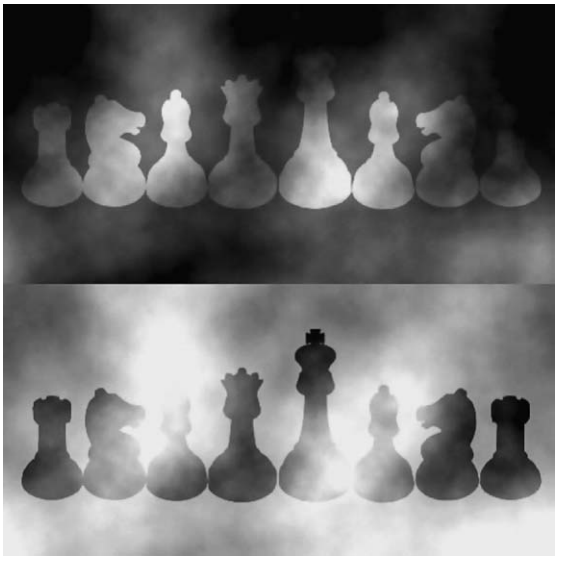

Figure 3 A figure demonstrating the role of scission on perceived lightness. The textures in the chess pieces on the top and bottom are identical; the only difference in the two images is the luminance distributions in the surrounds. From Anderson, B. L. and Winawer, J. 2005. Image segmentation and lightness perception. Nature 434, 79–83.

contrast between the king and the surround occurs along the bottom right of the piece, whereas the lowest contrast occurs along the top. Thus, the transmittance anchoring principle states that the bottom right of this figure should appear in plain view, which is white; whereas the reductions in contrast that occurs along the boundaries separating the king from its surround should signal the presence of a transparent medium that varies in opacity (being most opaque where the contrast of the boundary is lowest, which here, occurs along the top of the king). A similar analysis holds for the bottom figure, except now the polarity and magnitude relationships are reversed. In this image, the highest contrast region along the border separating the king from its surround occurs along its top, and hence, the transmittance anchoring principle predicts that this portion of the king (which is dark) should appear in plain view, and lower contrast regions along the contour should appear partially obscured by transparent media. In the bottom image, the lowest contrast region of the king-surround border occurs along the lower right of the image, and thus, the opacity of the transparent layer should be greatest in this region. This is consistent with what observers report.

In sum, the perception of transparency and lightness in Figure 3 reveals the close relationship between the perception of transparency, occlusion, and lightness. The perception of transparency involves the decomposition of an image into multiple layers, and the properties of the layers depend critically on exactly how luminance is partitioned between them. There is a growing body of data suggesting that the contrast relationships that occur along surfaces and contours play a critical role in determining when scission is initiated, as well as determining how surface properties such as lightness and opacity are attributed to the layers that are formed when this decomposition occurs. Such results reveal severe limitations on inverse optics models of perception, since the computation of properties such as the transmittance of transparent surfaces are almost always physically incorrect. Moreover, there is currently no single measure of image contrast that adequately captures perceived contrast in arbitrary images, which impedes the ability to predict the precise conditions that lead to scission and the quantitative consequences that scission should have on perceptual experience. It is therefore of critical importance to develop a measure of contrast that actually captures the human experience of contrast, so that it can be used to develop and assess theories of transparency perception. Finally, although phenomena such as those depicted in Figure 3 reveal that scission can have a dramatic effect on perceived lightness, more research is needed to determine if an explicit decomposition of images into layers is responsible for the perception of lightness (and color) in all images.

Glossary

CIP caudal intraparietal region. Located posteriorly on the lateral bank of the intraparietal sulcus (IPS) in the monkey.

correspondence problem To determine for each pixel in the pattern of one eye the matching pixel of the pattern in the other eye.

DIPSA Dorsal intraparietal sulcus anterior region in humans: located rostrally in the parietal part of the IPS, near junction with postcentral sulcus. Located posterior to human anterior intraparietal (hAIP) and anterior to the dorsal intraparietal sulcus medial (DIPSM). Originally defined as a motion-sensitive region.

DIPSM Dorsal intraparietal sulcus medial region in humans: located caudally on the horizontal or parietal part of the IPS, rostral from the

parieto-occipito intraparietal sulcus (POIPS). Originally defined as a motion-sensitive region.

disparity Difference in position relative to the fovea of retinal images in the two eyes. The differences can occur in the horizontal and vertical directions. Given the horizontal separation between the two eyes, the horizontal disparity differs between points at different distance from the fixation point (which projects onto the fovea).

FST Fundus of the superior temporal region, another satellite of MT/V5 in monkeys.

functional magnetic resonance imaging (fMRI) Imaging technique visualizing the hemodynamic responses in different parts of the brain (typically in voxels a few millimeters on the side). In humans, fMRI uses the BOLD (brain oxygen level-dependent) effect based on the paramagnetic properties of hemoglobin. In monkeys, a contrast agent is used: MION (monocrystalline iron oxide nanoparticle) or a very similar product, Sinerem (Guerbet, France). While BOLD reflects three variables: blood volume and flow and oxygen extraction, MION depends only on blood volume. This latter signal is not only much stronger than the BOLD effect (a factor five), but also reaches a maximum in the middle cortical layers, while BOLD peaks in the most superficial layers.

hAIP Human homolog of monkey anterior intraparietal (AIP) region. Identified by grasping movements.

hMT/V5+ Human homolog of MT/V5, supposedly includes the homologs of the MT/V5 satellites (as indicated by the +).

ITG Inferior temporal gyrus (human cortex).

LOC Lateral occipital complex. Despite its name most of this object or two-dimensional (2D) shape processing region is located ventral and anteroventral to hMT/V5+.

LOS Lateral occipital sulcus region: shape processing region posterior to hMT/V5+, was originally included in the definition of lateral occipital complex (LOC), but subsequently removed.

MSTd Medial superior temporal region, dorsal part, satellite of MT/V5 in monkey.

MT Area in the monkey; originally defined as V5, located caudally in the lower bank of the superior temporal sulcus (STS).

OTS Occipitotemporal sulcus separates inferior temporal gyrus (ITG) from fusiform gyrus in humans.

POIPS Parieto-occipito intraparietal sulcus region in humans, located at the junction of parieto-occipital sulcus and intraparietal sulcus (IPS), dorsal from the ventral intraparietal sulcus (VIPS). Originally defined as a motion-sensitive region.

Stereogram Stimuli presented to the two eyes to produce an impression of depth. Random-dot stereograms (RDSs) were introduced to study stereoscopic processing without contamination of edges or shape. Part of the pixels in the random-dot pattern of one eye is moved laterally over a small distance in the pattern of the other eye to induce a horizontal disparity. Thus, in a RDS each pixel of the random-dot pattern in one eye has a match in that of the other eye. When the pixels in the pattern of one eye are reversed in contrast all pixels in one eye are matched by one of opposite contrast in the other eye, yielding an anticorrelated RDS. If the pixels of the pattern of eye have a random relationship to those of the pattern in the other eye, the RDS is decorrelated. The coherence of the RDS is manipulated by changing the percentage of pixels that have a match in the other eye: a standard RDS has 100% coherence, a decorrelated RDS has 0% coherence.

TEs Small part of TE, the anterior part of the inferotemporal cortex, located in the lower bank of the superior temporal sulcus (STS) of the monkey.

Tilt and slant Basic parameters of three-dimensional (3D) surface orientation: tilt is the direction in which the surface is angled away from the frontoparallel plane (or equivalently the orientation of the axis around which the surface has been rotated) and the slant indicates how much it is angled away from the frontoparallel surface.

VIPS Ventral intraparietal sulcus region in humans, located in the bottom of the occipital part of the IPS, just dorsal of V3A. Originally defined as a motion-sensitive region.

2.15.1 Introduction

For years the combination of single-cell recording and psychophysics were considered the golden avenue to unravel sensory processing (LaMotte, R. H. and Mountcastle, V. B., 1975; Westheimer, G., 1979). This led to a number of studies in awake monkeys, in which, for a given stimulus dimension, perceptual performance, usually a discrimination threshold, was compared to single-cell encoding performance. Well-known examples are coarse and fine direction discrimination (Britten, K. H. *et al.*, 1992; Purushothaman, G. and Bradley, D. C., 2005), fine orientation discrimination (Vogels, R. and Orban, G. A., 1990), or disparity discrimination (Uka, T. and DeAngelis, G. C., 2003). Some of these studies have pursued the parallelism beyond the simple encoding of a stimulus dimension, investigating the neuronal basis of cognitive components of discrimination tasks such as decision processes (Shadlen, M. N. and Newsome, W. T., 2001) or temporal comparison of successive stimuli (Orban, G. A. and Vogels, R., 1998). These studies relied on anatomy to pinpoint the successive steps of processing to be investigated with single-cell recording. The correct choice is far from evident as most cortical regions project to many target areas and selecting the one involved in a particular cognitive component of a task generally involves a great deal of guesswork. Hence, progress has been slow.

Direct study of the sensory processing in the human brain became possible in the early 1990s with the development of functional magnetic resonance imaging (fMRI). This technique visualizes the cortical regions engaged by discrimination tasks (Sunaert, S. *et al.*, 2000; Faillenot, I. *et al.*, 2001; Shikata, E. *et al.*, 2001; Claeys, K. *et al.*, 2004), or even regions simply involved in the passive processing of different visual stimuli (Tootell, R. B. *et al.*, 1995; Hadjikhani, N. *et al.*, 1998; Sunaert, S. *et al.*, 1999; Bartels, A. and Zeki, S., 2000; Kourtzi, Z. and Kanwisher, N., 2000; Backus, B. T. *et al.*, 2001; Denys, K. *et al.*, 2004). Furthermore, with the advent of fMRI in awake monkeys (Vanduffel, W. *et al.*, 2001; Nakahara, K. *et al.*, 2002), direct links can be established between human fMRI and single-cell studies in the monkey. First, comparing fMRI responses in the two species allows the investigator to advance the question of homology, or at least functional equivalence, between cortical regions in the two species. Second, comparing the fMRI responses and the single-cell responses in the awake monkey allows derivation of the fMRI signature of the neuronal property under investigation, or the reverse. The macroscopic view provided by monkey fMRI is a useful complement to the detailed description of the activity of a single neuron, out of the billions of neurons contributing to a given function, provided by single-cell recording. In fact, the monkey fMRI technique represents a golden scouting opportunity for finding cortical areas engaged in a given type of processing. These areas can then be targeted by more specific, but also more labor-intensive techniques, such as single-cell recording, electrical stimulation, or inactivation studies. This promises to accelerate the progress of monkey studies.

The triad of systems neuroscience techniques – single-cell recording and fMRI in awake monkey and human fMRI – has been applied to the question of extracting three-dimensional (3D) shape from the motion cue. Hence this chapter endeavors, for the first time, to integrate the results from the three techniques addressing the same question. Although efforts have also been directed towards the extraction of 3D shape from other cues such as stereo, texture, and shading (Janssen, P. *et al.*, 2002; Tsutsui, K. *et al.*, 2002; Georgieva, S. *et al.*, 2003a; 2003b; 2005; Durand, J. B. *et al.*, 2007), less progress has been achieved so far. Hence, the overview will have to be much more limited for these other cues.

2.15.2 The Visual Ecology and Perception of Three-Dimensional Shape

2.15.2.1 Orders of Depth

Although the processing of depth and 3D shape has a common origin in the loss of the third dimension at the level of retinal transduction and is based on similar cues, these two perceptual aspects have to be sharply distinguished. Depth is a property of space and 3D shape a property of objects. In order to distinguish 3D-shape processing from simple depth processing, it is useful to remember the different orders of depth (Figure 1). Zero-order depth corresponds to fronto-parallel planes at different distances from the observer or from the fixation plane. For the disparity cue this corresponds to a stimulus with constant disparity, provided the stimuli are sufficiently small and sufficiently close to the median plane (Howard, I. P. and Rogers, B., 2002). While absolute disparity references a fronto-parallel plane to the fixation point, relative disparity (Howard, I. P.

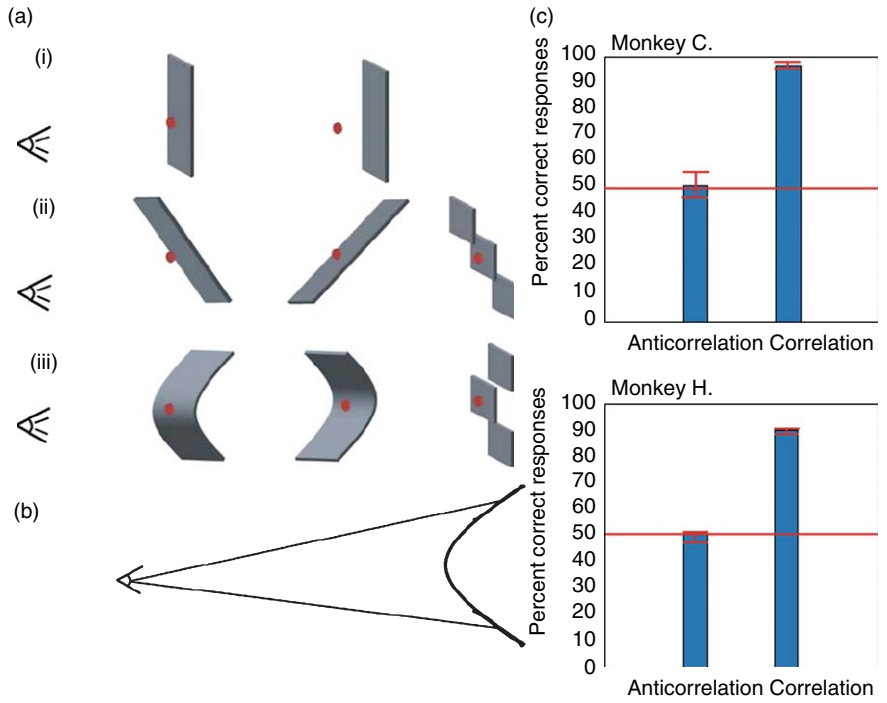

Figure 1 Orders of depth and monkey perception. (a) 3D surfaces (side view) at different positions from the fixation point (red dot), seen from the left (eye icon) portraying variations in different depth orders: zero order (i), first order (ii) and second order (iii). Approximations by zero order are indicated in (b) and (c). Notice that in the first and second-order disparity stimuli presented on computer screens, disparity also changed in discrete steps, but these steps were very small (2 minarc). (b) Viewing of curved surface with an indication of tilted planes (dark lines) giving rise to disparity gradients. (c) Percent correct responses of monkeys C and H for distinguishing between convex and concave surfaces in anticorrelated RDS and correlated RDS. With kind permission from Orban, G. A., Janssen, P., and Vogels, R. 2006b. Extracting 3D structure from disparity. Trends Neurosci. 29, 466–473.

and Rogers, B., 1995) references it to another reference plane in depth. First-order depth refers to planar surfaces tilted in depth; for disparity this corresponds to a linear gradient of disparity. For motion it corresponds to a linear gradient in speed (Gibson, J. J., 1950), for texture to gradients in size, foreshortening, and density (Hillis, J. M. *et al.*, 2004). Finally, second-order depth corresponds to surfaces curved in depth, for example, a surface with a constant, nonzero value of the second-spatial derivative of disparity. This second derivative can be taken in either the horizontal or vertical direction, yielding a horizontally or vertically curved surface, respectively. Again, for motion and texture, curvature in depth corresponds to second-order derivatives in speed or any of the three texture cues. Note that a higher-order depth input can be approximated by steps in a lower-depth order.

In the case of disparity it is well known that the second-spatial derivative is independent of the distance from the observer (Figure 1) and hence is an intrinsic property of the object (Rogers, B. and Cagenello, R., 1989). First-order disparity can either be intrinsic to an object that is bound by tilted planes, or extrinsic as it can represent the overall orientation of an object in space. Thus second-order depth, and to some extent first-order depth, capture rather well local aspects of 3D shape (Koenderink, J. J., 1990), but more global aspects also contribute to 3D-shape processing especially from texture and shading (Todd, J. T., 2004; Todd, J. T. *et al.*, 2005).

At this point it is worth remembering that 3D structure can also be a property of the visual environment, something sometimes referred to as the 3D layout of the environment. This 3D structure of the visual scene is a critical aspect for, for example, walking or climbing. Since most of the stimuli used in the reported investigations were relatively small, they relate mainly to processing of the 3D shape of objects. This latter processing is critical for grasping and manipulating objects (Watt, S. J. and Bradshaw, M. F., 2003) and in some instances for identification

or categorization (e.g., balls vs. disks). Thus in this review 3D structure is the more general term. For small stimuli, 3D structure and 3D shape will be used interchangeably.

2.15.2.2 Cues for Three-Dimensional Shape and Stimuli

The main cue for 3D shape is the stereo cue which allows the complete recovery of 3D shape including its sign (convex vs. concave curvatures). This cue can be carried by surfaces or edges. Examples of the latter are the images of elongated objects tilted or curved in depth (Sakata, H. *et al.*, 1998) as well as the multiple connected random lines, images of wireframe objects or paperclips (Edelman, S. and Bülthoff, H., 1992; Orban, G. A. *et al.*, 1999). In experimental settings, surfaces in depth are frequently portrayed by random-dot stereograms (RDS, Julesz, B., 1971). Given the two-dimensional (2D) shape selectivity of most IT neurons (Gross, C. G. *et al.*, 1972) we (Janssen, P. *et al.*, 1999) have frequently used a special type of random stereogram enclosed in a 2D shape. Such bounded surfaces can be characterized by a texture inside the boundary and the boundary, both of which carry depth information. So-called solid figure stereograms (Shikata, E. *et al.*, 1996), by contrast, only carry depth information at the boundaries.

Motion is also a potent cue for 3D structure (Gibson, J. J., 1950). When the observer is moving the motion parallax will provide information about the layout of the environment (Rogers, B. and Graham, M. E., 1979). When the observer is stationary different parts of a moving object will move at different speeds if they are at different distances from the eye. Both aspects of linear motion parallax can be unified in optic flow, which arises from the relative movement between the observer and the environment and provides not only information about motion of the observer or the environment but also about the 3D layout of the environment. Linear parallax differs from another type of motion parallax: the kinetic depth effect (Wallach, H. and O'Connell, D. N., 1953), in which vivid 3D structure is perceived when portraying an object that rotates around a frontal axis.

3D shape can also be recovered from a wide range of cues other than motion and disparity (Norman, J. F. *et al.*, 2004), such as occlusion, shading, and specular highlights, as well as texture. Shading and texture require surface stimuli either bounded surfaces, that is, portraying objects, such as the randomly deformed spheres introduced by Todd J. T. *et al.* (1997), or unbounded surfaces, that is, portraying the environment. Occlusion characterizes, by definition, bounded surfaces, including silhouettes. In edge-type stimuli, static monocular cues include perspective for the first-order case and closure based on T-junctions, portraying a volume, for example, a polyhedron, bounded by edges (Orban, G. A. *et al.*, 1999) for the second-order case.

2.15.2.3 Human Perception of Three-Dimensional Shape

Stereo and motion are two powerful cues for 3D shape perception. Motion sequences with three or more views and binocular displays with both horizontal and vertical disparities allow in theory a complete and unambiguous determination of the object 3D shape. Stereo does specify the sign of the curvature (convex and concave). Motion, however, does so under perspective projection, but not under orthographic projection (Braunstein, M. L., 1977). The neuronal processing of these two cues is quite distinct. This probably explains why humans are more sensitive for stereo than for motion parallax in detecting corrugations in depth (Rogers, B. J. and Graham, M. E., 1979; Bradshaw, M. F. and Rogers, B. J., 1999). Texture is a less powerful cue for 3D shape and the shading cue has strong inherent limitations (Belhumeur, P. N. *et al.*, 1999). Yet all of these cues allow fine distinction to be made between different shapes (Norman, J. F. *et al.*, 2004). In particular, these four cues, including shading, allow sensitive distinctions between different values of the shape index (Figure 2), provided the visual information is presented in patches of at least 3–4° in diameter (Phillips, F. and Todd, J. T., 1996). This index, based on the ratio of curvatures along two orthogonal lines, captures the local 3D shape (Howard, I. P. and Rogers, B. J., 2002). Further studies have shown that at a more local level (around a point of the surface) curvedness and shape index may not be represented independently, while slant and tilt are (Norman, J. F. *et al.*, 2006).

Three cues – stereo, motion, and texture – support qualitatively correct 3D shape perception: the perceived 3D shape correlates with the 3D shape of the depicted surfaces (e.g., Sperling, G. *et al.*, 1990 for the motion cue). Correlations are also high between observers or across multiple sessions of a given observer. Thus observers correctly perceive the pattern of

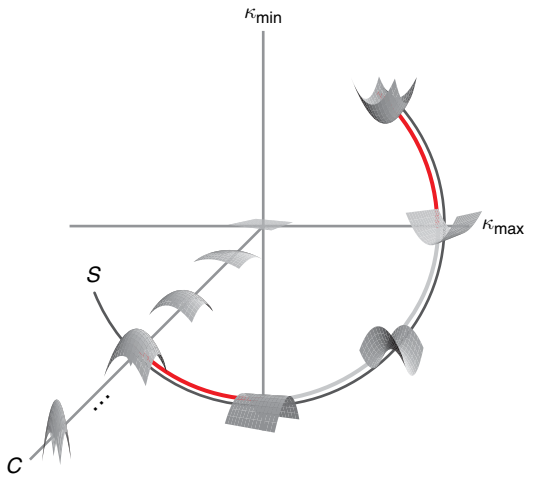

Figure 2 Shape index (S) and curvedness (C) defined from two orthogonal single curvatures (κ_{min} and κ_{max}). With kind permission adapted from Norman, J. F., Todd, J. T., Norman, H. F., Clayton, A. M., and McBride, T. R. 2006. Visual discrimination of local surface structure: slant, tilt, and curvedness. Vision Res. 46, 1057–1069.

concavities and convexities of 3D objects. Yet, there is mounting evidence that the metric aspect of 3D shape is not well perceived. Even for motion and disparity cues, the 3D shape perceived is different from the physically specified structure (the slope of the line expressing perceived depth as a function of veridical depth is significantly different from unity) and varies considerably depending on experimental conditions (Todd, J. T. and Norman, J. F., 2003). For motion or stereo the amount of perceived depth or magnitude of the relief deviates from the real values by up to 30–40% and this deviation depends on distance or the task. For the less powerful texture cue (Todd, J. T. *et al.*, 2004) the magnitude of the relief is strongly underestimated (up to 75%). Thus the processing of these three cues allows the building of a representation of 3D shape that is correct up to a stretch factor, that is, one that is related to the real 3D shape by an affine stretch transformation. The representation built up from the shading cue is of a different nature, however, since the correlation of perceived shape between observers or between tasks for a given observer can be close to zero. Subsequent analyses have revealed that most of the perceptual variance could be removed by an affine shearing transformation in depth rather than a simple stretching (Koenderink, J. J. *et al.*, 2001).

The obvious answer to the lack of reliability of single cues is to combine their information. But even under conditions where the full complement of cues is available, the metric structure is still perceived inaccurately (Todd, J. T. and Norman, J. F., 2003). This raises the issue whether the cues are combined at all. Recent studies (Knill, D. C. and Saunders, J. A., 2003; Hillis, J. M. *et al.*, 2004) have indeed indicated that at least for slant judgments, cues are combined according to an optimal rule which follows Bayses' rule: the cues are weighted according to their reliability. Similar combination rules have also been demonstrated for judgments combining inputs from different senses (Ernst, M. O. and Banks, M. S., 2002). Not only are 3D shape cues combined, it has been argued that within the sense of vision, the fusion of cues is mandatory and that individual cues cannot be accessed by perception (Hillis, J. M. *et al.*, 2002). This would imply that at higher levels, 3D shape is represented in a cue invariant manner.

2.15.2.4 Monkey Perception of Three-Dimensional Structure

Since many of the studies reviewed involve monkeys rather than human subjects, it is important to ascertain whether or not monkeys perceive 3D shape from the various cues and how similar their perception is to that of human subjects.

Siegel R. M. and Andersen R. A. (1988; 1990) provided evidence that monkeys perceived 3D structure from motion (SFM) and that their perception is relatively similar to that of humans. They used a task in which subjects have to signal the change from an unstructured to a structured display, where structure can be an optic flow component (expansion, or rotation) or 3D shape. Reaction times were longer and the amount of structure needed was larger for the 3D shape than the flow components suggesting more complex processing was necessary for performing the 3D task. This conclusion was also supported by the longer point lifetime (timepoint remains visible) and the larger number of points in the display required in the 3D task. These lifetime and number-of-points thresholds were relatively similar for the two species. The stimulus used in this 3D task, a rotating transparent cylinder, was also used in another task, sometimes referred to as a 3D shape discrimination task (Bradley, D. C. *et al.*, 1998; Dodd, J. V. *et al.*, 2001). The stimulus is bistable, given the ambiguity of motion parallax, and the monkey simply has to indicate whether the dots on the front surface appear to move to the right or left. While this task requires the distinction between two surfaces in depth it is not clear whether it requires analysis of

the shape of the front or back surfaces. Hence, it is more correctly considered an order in depth task (Born, R. T. and Bradley, D. C., 2005).

Monkeys can make a distinction between convex and concave 3D surfaces specified by disparity (Figure 1; Janssen, P. *et al.*, 2003). This judgment depends on stereo coherence just as in humans (Liu, Y. *et al.*, 2002). As in humans, this perception vanishes when correlated stereograms are replaced by anticorrelated (see Glossary) stereograms (Figure 1; Janssen, P. *et al.*, 2003).

Finally, there is also indirect evidence that monkeys perceive 3D shape from texture. After training in matching two stereo-specified planar 3D surfaces, monkeys can match a texture-specified slanted planar surface with a stereo-specified surface (Tsutsui, K. *et al.*, 2002). Similarly, monkeys trained to distinguish convex from concave surfaces specified by both stereo and texture can make similar distinctions when the stereo cue reliability is strongly compromised by reducing its coherence. However, the discrimination performance, while significantly different from random choice, was relatively weak and much lower (in % correct) than that of humans (Liu, Y. *et al.*, 2002).

2.15.3 The Extraction of Three-Dimensional Shape from Motion

The extraction of 3D SFM has been studied at multiple levels in the monkey using single-cell recording and fMRI. Furthermore the same fMRI paradigms have been used in humans and awake monkeys allowing direct functional comparison. We will follow the historical order in which the relevant experiments were performed, starting with single-cell recording.

2.15.3.1 Single-Cell Studies

Most studies have used linear speed gradients, the direction of which corresponds to the tilt of a 3D surface (direction in which a 3D surface is angled away from a fronto-parallel plane). In MT/V5 studies these gradients have been superimposed onto fields of translating dots, in medial superior temporal dorsal part (MSTd) studies onto flow components.

2.15.3.1.1 Area MT/V5

Initially, two alternative views have been proposed as mechanisms for the detection of speed gradients: hotspots in the receptive field (RF) itself (Treue, S. and Andersen, R. A., 1996) or a surround-based mechanism (Xiao, D. K. *et al.*, 1995). Subsequent work has indicated that the main mechanism is surround based. In anesthetized monkeys, about 50% (27/57) of MT/V5 neurons were selective for the direction of the speed gradient (Figure 3) and different neurons were tuned to different tilts (Xiao, D. K. *et al.*, 1997a). This tilt selectivity critically depended on the surround since all of the selective neurons had antagonistic surrounds and the selectivity was strongly reduced when the surround was masked (Figure 3). Further studies (Xiao, D. K. *et al.*, 1997b) showed that the majority of MT/V5 neurons have nonhomogeneous antagonistic surrounds, as predicted by computational models (Baracas, G. T. and Albright, T. D., 1996; Gautama, T. and Van Hulle, M. M., 2001). Figure 4 illustrates the stimuli used to map the excitatory RF (ERF, A), to unmask the presence of a surround (spatial summation test, B) and to map the spatial distribution of the surround effects either coarsely (in one of eight directions around the ERF, C) or in detail (same spacing as excitatory mapping, D). The neuron in Figure 4 had a strong surround effect (F) which arose from an antagonistic region located above the ERF (G and H). Such unimodal surrounds allow the neuron to compute a spatial derivative of speed (thus a gradient) provided the inhibitory surround influence is itself speed dependent. In many MT/V5 neurons this is indeed the case, as shown in Figure 5. This MT/V5 neuron had a strongly asymmetric surround but only when the stimuli in the surround moved at the same or faster speed than the dots moving over the ERF.

These studies in anesthetized monkeys have been replicated recently by Nguyenkim J. D. and DeAngelis G. C. (2004) in awake monkeys by using large stimuli involving the surround, similar to those used by Xiao D. K. *et al.* (1997a). These authors confirmed the selectivity of MT/V5 neurons for speed gradients (Figure 6) and provided an important control test: the selectivity for the speed gradient is invariant with respect to the average speed in the display. Furthermore, they showed that MT/V5 neurons are frequently selective for disparity gradients and occasionally even texture gradients, but to a lesser degree than for speed gradients. Furthermore, the selectivity for the three cues combined reflected largely that for the speed gradients (Nguyenkim, J. D., personal communication). Although the optimal tilt for the different gradients was not always congruent, Nguyenkim J. D. and DeAngelis G. C. (2004) obtained evidence for increased selectivity when cues were combined.

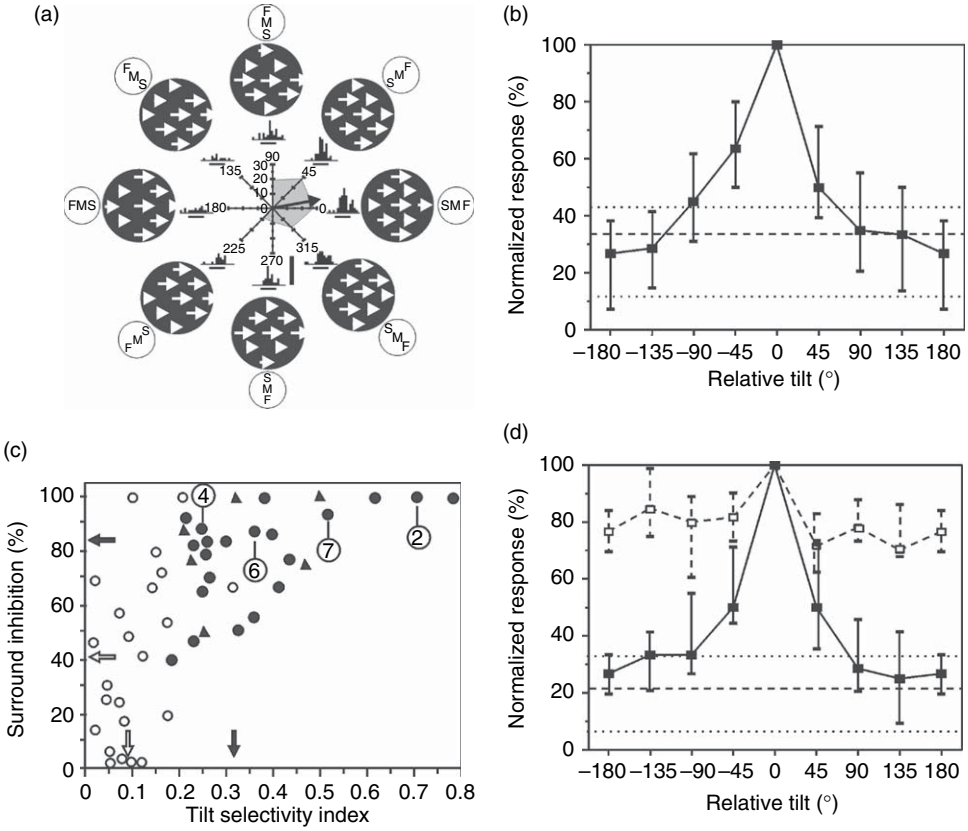

Figure 3 Selectivity of MT/V5 neurons for speed gradients corresponding to tilt in depth of 3D planar surfaces. (a) Tuning of neuron 8228 plotting net firing rate as a function of tilt direction. For each tilt the poststimulus time histogram (vertical bar 50 spikes s^{-1}) and speed gradient is shown pictorially or schematically (S, slow; M, medium; F, fast). (b) Average tuning for 27 selective neurons. (c) Plot of surround strength (in %) as a function of selectivity for tilt (SI): filled symbols, selective neurons; arrows, medians for selective (filled) and nonselective (open) neurons; numbers refer to example neurons in Xiao D. K. *et al.* (1997a). (d) Tuning curve of seven selective neurons with surround in view (full lines) or masked (dotted lines). In (b) and (d) the horizontal lines indicate the median and quartiles of responses to a fronto-parallel surface of same size as gradients (25.6°). With kind permission from Xiao, D. K., Marcar, V. L., Raiguel, S. E., and Orban, G. A. 1997a. Selectivity of macaque MT/V5 neurons for surface orientation in depth specified by motion. Eur. J. Neurosci. 9, 956–964.

The selectivity of MT/V5 neurons for disparity gradients might similarly be surround based as MT/V5 neurons also have surround effects in the disparity domain (Bradley, D. C. and Andersen, R. A., 1998). Nguyenkim J. D. and DeAngelis G. C. (2003), however, provided evidence that they rather arose from heterogeneities in the RF. This latter finding further suggests that the selectivity for disparity gradients does reflect spatial variations in position disparity rather than orientation disparity. That the gradient selectivity for disparity arises from the RF, while that for speed arises from interaction between the surround and the RF might reflect the difference in coding of speed and disparity at this level. Speed tuning of MT/V5 neurons is rather coarse (Maunsell, J. H. R. and Van Essen, D. C., 1983a; Lagae, L. *et al.*, 1993; Priebe, N. J. *et al.*, 2003) while that of disparity is finer (Maunsell, J. H. R. and Van Essen, D. C., 1983b; DeAngelis, G. C. and Uka, T., 2003). Hence, to capture a given value of a gradient a larger distance may be required for speed than disparity, explaining the need to resort to RF surround interactions to extract speed gradients.

Finally, one study reported an impairment of SFM perception after lesion of MT/V5 (Andersen, R. A. *et al.*, 1996), indicating that this area is a critical component of the 3D shape from motion extraction pathway.

2.15.3.1.2 Beyond MT/V5

Selectivity for speed gradients has also been documented in MSTd, a region receiving input from MT/V5 and which is know to process optic flow

(Ungerleider, L. G. and Desimone, R., 1986; Saito, H. *et al.*, 1986; Duffy, C. J. and Wurtz, R. H., 1991, Lagae, L. *et al.*, 1994; Graziano, M. S. *et al.*, 1994). Duffy C. J. and Wurtz R. H. (1997) noted that the speed gradients superimposed on flow components significantly affected the firing of MSTd neurons in awake monkeys. Sugihara H. *et al.* (2002) superimposed speed gradients onto rotatory flow, producing rotating planes with various 3D orientations. A substantial fraction (43/97) of MSTd neurons were selective for the tilt of the speed gradient. Selectivity for slant (the amount by which the 3D surface is angled away from the fronto-parallel plane) was also observed in nearly half the MSTd neurons.

In the anterior superior temporal polysensory (STPa) area, neurons are also selective for optic flow components (Anderson, K. C. and Siegel, R. M., 2005; Nelissen, K. *et al.*, 2006), and a fraction of them are selective for 3D SFM (Anderson, K. C. and Siegel, R. M., 2005). These authors used a transparent sphere similar to the hollow cylinder used in the perceptual experiments of Siegel R. M. and Andersen K. C. (1990). While this stimulus is characterized by second-order speed variations, it does not allow parameters describing the surface to be easily manipulated. A number of STPa neurons responded at the onset of 3D SFM and some of these were selective for the axis or rotation and were size invariant.

2.15.3.2 Human Imaging Studies

2.15.3.2.1 Human MT/V5+

It is generally accepted that human MT/V5+ (hMT/V5+) represents the homolog of monkey MT and its satellites, including MSTd (Zeki, S. *et al.*, 1991; Tootell, R. B. *et al.*, 1995; DeYoe, E. A. *et al.*, 1996; Orban, G. A. *et al.*, 2004). Hence, the single-cell results reviewed above predict that hMT/V5+ should be involved in extracting 3D SFM. This was the hypothesis tested by our initial imaging study (Orban, G. A. *et al.*, 1999). hMT/V5+ was indeed more active when subjects viewed rotating random lines portraying a 3D shape than when they saw the same lines translating at uniform speed. In fact, the dimensionality of structure and rigidity of the shape were manipulated independently in this experiment and the stronger magnetic resonance response to 3D compared to 2D structure held up for both rigid and nonrigid shapes (Figure 7). Several controls were performed, as illustrated in Figures 7(c)–7(e). hMT/V5+ activation by 3D SFM exceeded that of various 2D controls in which low-level motion factors such as speed or range of directions were manipulated, that of a 2D control to which attention of the subject was attracted and that evoked by a combination of 3D shape and motion (moving polyhedra, using the closure cue for 3D shape).

The rotating random-line stimuli used in Orban G. A. *et al.* (1999) still contained two perceptual aspects which both could have caused the hMT/V5+ activation: motion of the lines along 3D trajectories and a 3D shape. These two stimulus aspect are nondissociable in dynamic 3D SFM displays and, hence, we had to resort to an active experiment, in which we asked subjects to pay attention to one of the two aspects. Thus, in the Peuskens H. *et al.* (2004) study subjects faced randomly deformed 3D spheres rotating around near-vertical axes and made three same–different judgments: about the 3D shape, the axis of rotation (pattern of 3D motion), or the texture on the surface of the sphere (Figure 8). In addition, in two lower control conditions they detected the dimming of central or peripheral parts of the objects. hMT/V5+ was significantly more active when subjects made 3D shape or 3D motion judgments than when they made the texture judgments, indicating that hMT/V5+ is indeed processing features related to 3D shape, extracted from motion.

Finally, one could argue that the random-line stimuli were very different from the stimuli used in the single-cell studies (Xiao, D. K. *et al.*, 1997a). To ensure the generality of the hMT/V5+ activation by 3D SFM we (Orban, G. A. *et al.*, 2006a) again tested passive subjects with random lines portraying the sides of a randomly oriented cube and random dots portraying a sphere rotating around a vertical axis. In addition to dimensionality of structure (3D vs. 2D) and lines versus dots, we manipulated a third factor: transparency. hMT/V5 displayed a significant main effect for 3D compared to 2D structure in the 3×2 design, as well as in each of the four 2×2 subdesigns (for opaque and transparent surfaces, for dot and lines surfaces), confirming the generality of its engagement by 3D shape extraction (see also Vanduffel, W. *et al.*, 2002). This does not mean that these other factors had no effect on the activation of hMT/V5+ by 3D shape stimuli compared to 2D shapes. This differential activation was stronger for opaque than for transparent stimuli and also for random lines than random-dot stimuli (Figure 9).

The activation of hMT/V5+ by SFM was confirmed by Kriegeskorte N. *et al.* (2003) using a SFM stimulus (on-surface SFM) derived from a technique initially developed by Perotti V. J. *et al.* (1996): hMT/

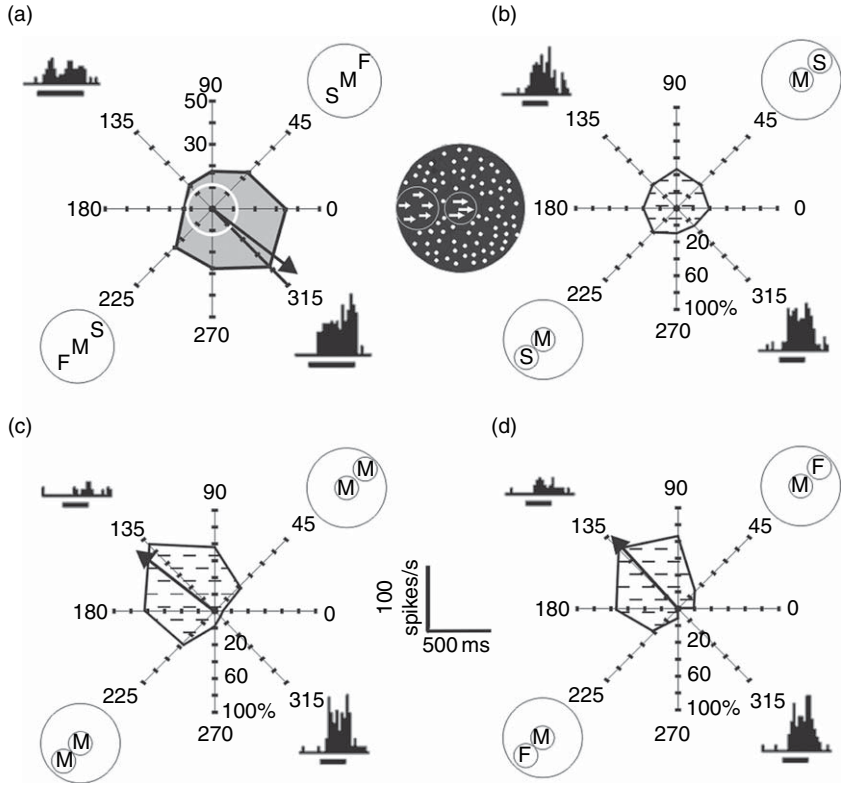

Figure 5 Speed dependence of surround effects in MT/V5 neurons. Tilt tuning of neuron 8207 (a) and the asymmetry of the surround tested at three relative speeds: slower than center (b), same speed as center (c), and faster than center (d). Same conventions as Figures 3 and 4; With kind permission from Xiao, D. K., Marcar, V. L., Raiguel, S. E., and Orban, G. A. 1997a. Selectivity of macaque MT/V5 neurons for surface orientation in depth specified by motion. Eur. J. Neurosci. 9, 956–964.

V5+ was significantly more active in on-surface SFM when the implicit object was moving (as in classical SFM) than when it was stationary, even if these two flow fields were extremely similar. This study also confirmed another conclusion drawn from our studies: stimulus differences affect the level of hMT/V5+ activation by SFM stimuli. These stimulus effects may explain why two studies (Paradis, A. L. *et al.*, 2000 and Murray, S. O. *et al.*, 2003) did not observe hMT/V5+ activation by SFM stimuli: both studies used transparent random-dots stimuli which are less effective in driving hMT/V5+. Furthermore, both used scrambled dots as a control rather than uniformly translating stimuli. Scrambled dots activate hMT/V5 much more than uniformly translating dots (Figure 9), because they contain many more motion directions. Their effect might be similar to flickering dots which also activate MT/V5+ strongly (Figure 7A). Had these flickering stimuli been used as controls rather than static stimuli, hMT/V5+ might never have been discovered!

These experiments show that hMT/V5+ is involved in the extraction of 3D shape from motion for a wide variety of displays, but the exact degree of the activation by 3D shape stimuli, relative to control stimuli, does depend on the particular stimulus conditions.

Figure 4 Asymmetry of surrounds of MT/V5 neurons. (a–d) Stimulus diagrams for 2D position test (a), spatial summation test (b), surround asymmetry test (c), and surround mapping test (d). Arrows indicate moving dots, surround mapping in C and D required two stimuli. (e–h) Results of the four tests for MT/V5 neuron 7916. (e, h) Color maps of excitation (red) and suppression (blue). In (f) and (g) response is plotted as a function of stimulus diameter (f) or test position of the stimulus in surround (g). In (f)–(h), sample peristimulus time histograms (PSTHs) are shown, including complete and no surround stimulation in (g). Arrow in (g) points to strongest suppression in surround which matches a similar indication by the asterisk in (h). With kind permission from Xiao, D. K., Raiguel, S., Marcar, V., and Orban, G. A. 1997b. The spatial distribution of the antagonistic surround of MT/V5 neurons. Cereb. Cortex 7, 662–677.

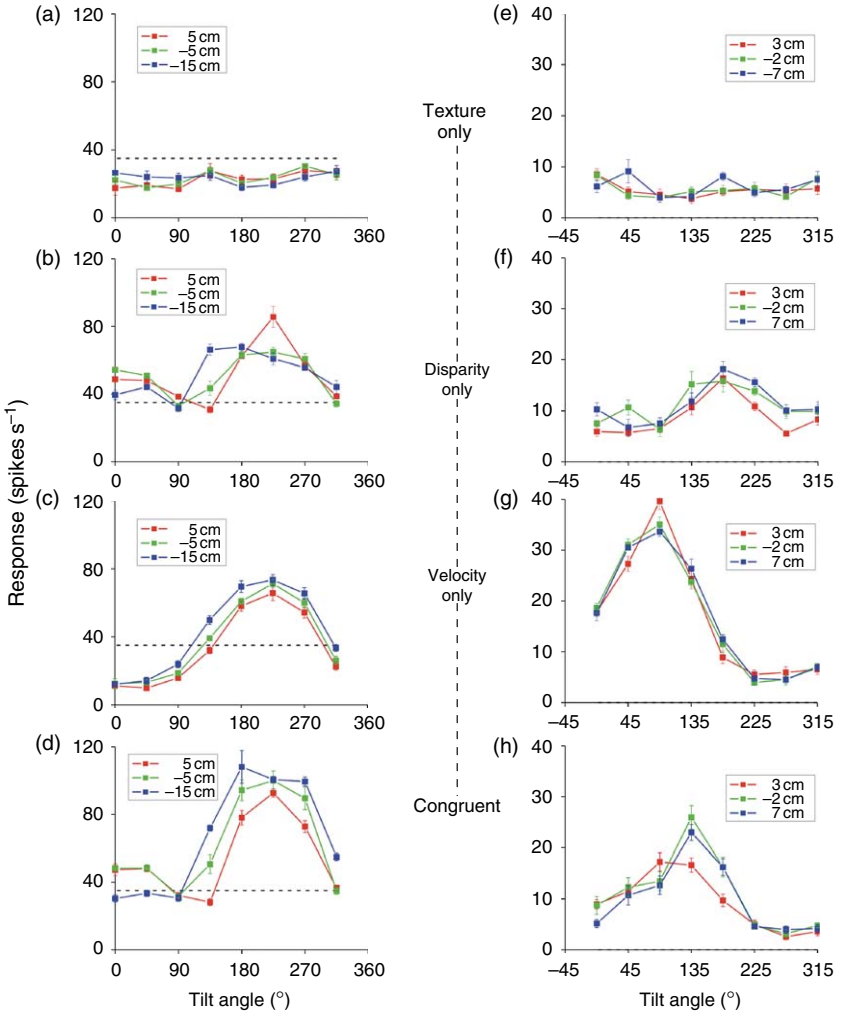

Figure 6 Tilt selectivity of two MT/VR neurons in awake monkey for three cues and their combination (Nguyenkim, J. D. and DeAngelis, G. C., 2004). Tilt tuning curves at three different mean depths (relative to fixation point, color coded) in the texture only condition (a and e), the disparity only condition (b and f), the speed only condition (c and g), and the congruent condition (d and h). The stimulus parameters for the neuron in a–d were: direction of motion 135°, speed of motion 32 cm s^{-1}, aperture diameter 24 cm, eccentricity 3.4 cm, slant 65°; for the neuron in (e)–(h): direction 0°, speed 8.4 cm s^{-1}, aperture diameter 28 cm, eccentricity 10.9 cm, slant 65°. At the distance from the screen used 1 cm = 1°. With kind permission from Nguyenkim J. D. (2005).

2.15.3.2.2 V3A and parietal regions

In each of the four studies (Orban, G. A. *et al.*, 1999; Vanduffel, W. *et al.*, 2002; Peuskens, H. *et al.*, 2004; Orban, G. A. *et al.*, 2006a) mentioned above, 3D SFM also engaged parietal regions near the intraparietal sulcus (IPS). In the passive experiments, V3A (referred to as transverse intraparietal sulcus (TRIPS) in Orban, G. A. *et al.*, 1999) and four IPS regions were activated by 3D SFM stimuli (Figure 10): the ventral intraparietal sulcus (VIPS) region in the occipital part of the IPS, just dorsal of region V3A; the parieto-occipito intraparietal sulcus (POIPS) region at the junction of the IPS and parietal occipital sulcus; the dorsal intraparietal sulcus medial (DIPSM) region (referred to as DIPSL in Orban, G. A. *et al.*, 1999), and the dorsal intraparietal sulcus anterior (DIPSA) region in the horizontal or dorsal part of IPS (for homology of these regions with macaque IPS regions see Orban, G. A. *et al.*, 2006a). These four parietal regions are also motion sensitive, just as hMT/V5+ is (Sunaert, S. *et al.*, 1999) and differ in the part of the visual field they represent: DIPSM and DIPSA represent the central visual field, POIPS the peripheral part, and VIPS both (Orban, G. A. *et al.*, 2006a). In the active experiment (Peuskens, H. *et al.*, 2004), DIPSM was active when subjects made same-different judgments about 3D shape, while DIPSA was active both when they made both

3D shape and 3D motion judgments. This latter activity was part of a wider, more anterior activation centered in the human anterior intraparietal (hAIP) region (Binkofski, F. *et al.*, 1999).

Parietal activations were also observed by Paradis A. L. *et al.* (2000), Murray S. O. *et al.* (2003), and Kriegeskorte N. *et al.* (2003). In fact, according to stereotaxic coordinates, the region defined as mid-lateral parietal cortex by Murray S. O. *et al.* (2003) and as IPS by Kriegeskorte N. *et al.* (2003) is close to DIPSA, underscoring its involvement in 3D SFM. The region near the occipito-parietal junction described by Paradis A. L. *et al.* (2000) might correspond to VIPS and POIPS which both respond relatively well to opaque random-dot 3D stimuli compared to scrambled dots (table 1 of Orban, G. A. *et al.*, 2006a).

2.15.3.2.3 Lateral occipital sulcus and ventral regions

Finally, a number of middle occipital and ventral, occipitotemporal regions are also engaged by 3D SFM. The activation of the region between V3/V3A and hMT/V5+, which we refer to as lateral occipital sulcus (LOS) (following the original Malach, R. *et al.*, 1995 study), was observed in all our passive and active studies (Orban, G. A. *et al.*, 1999; Vanduffel, W. *et al.*, 2002; Peuskens, H. *et al.*, 2004; Orban, G. A. *et al.*, 2006a). It may include the region referred to as SLO by Murray S. O. *et al.* (2003).

Some studies have indicated that ventral V3 might have been engaged by SFM: Vanduffel, W. *et al.* (2002), in which retiotopic regions were mapped, Orban G. A. *et al.* (1999), where it probably corresponds to the collateral sulcus region, and Paradis A. L. *et al.* (2000), who described a similar region as the occipitotemporal junction. The activation of V2 and V3 by 3D SFM might depend on the stimuli used, and was stronger with the random lines at right angles (Vanduffel, W. *et al.*, 2002) than at random angles (Orban, G. A. *et al.*, 1999, main experiment).

Finally subparts of 0LO complex might be engaged by 3D SFM, in particular the region immediately ventral to the hMT/V5+ complex (Figure 10). This region has been described as Fus/inferior temporal gyrus (ITG) in Orban G. A. *et al.* (1999), posterior ITG in Peuskens H. *et al.* (2004), and mid-occipitotemporal sulcus (OTS) in Orban G. A. *et al.* (2006a). It is a candidate region for cue convergence, as static monocular 3D shape cues also activate this region (Georgieva, S. *et al.*, 2003a; 2003b), as well as 3D structure from stereo (Figure 11) and tactile 3D shape cues (Amedi, A. *et al.*, 2001; James, T. W. *et al.*, 2002). Kriegeskorte N. *et al.* (2003) demonstrated a 3D SFM activation of the fusiform face area (FFA) when face stimuli but not when random stimuli were presented. This raises the possibility that other parts of lateral occipital (LO) might be activated by meaningful stimuli portrayed by 3D SFM. Alternatively, this 3D shape processing might be restricted to faces, as these seem to be processed in a separate manner (Kanwisher, N. *et al.*, 1997; Tsao, D. Y. *et al.*, 2006).

2.15.3.2.4 Cue combination

Most 3D shape imaging studies have so far used single cues. A notable exception is Welchman A. E. *et al.* (2005), who studied the combination of disparity and perspective cues in slant. These authors report specific effects of cue combination in hMT/V5+ and lateral occipital complex (LOC). The rebound from adaptation effects were larger for the two cues combined than for single cue. Although the interpretation of fast adaptation magnetic resonance techniques is far from straightforward (Sawamura, H. *et al.*, 2006), this might indicate greater selectivity for combined cues. We have observed negative interactions between 3D shape cues: the differential effect of 3D SFM was larger for 2D stimuli than for 3D shape stimuli whether the 3D shape was created by the closure cue, as in the Orban G. A. *et al.* (1999) control experiment (Figure 7F) or by disparity (Figure 7F; Figure 11). This reduced activation is compatible with narrower tuning curves, that is, stronger selectivity. Interestingly, this effect disappeared when the two cues were in conflict (Figure 7F).

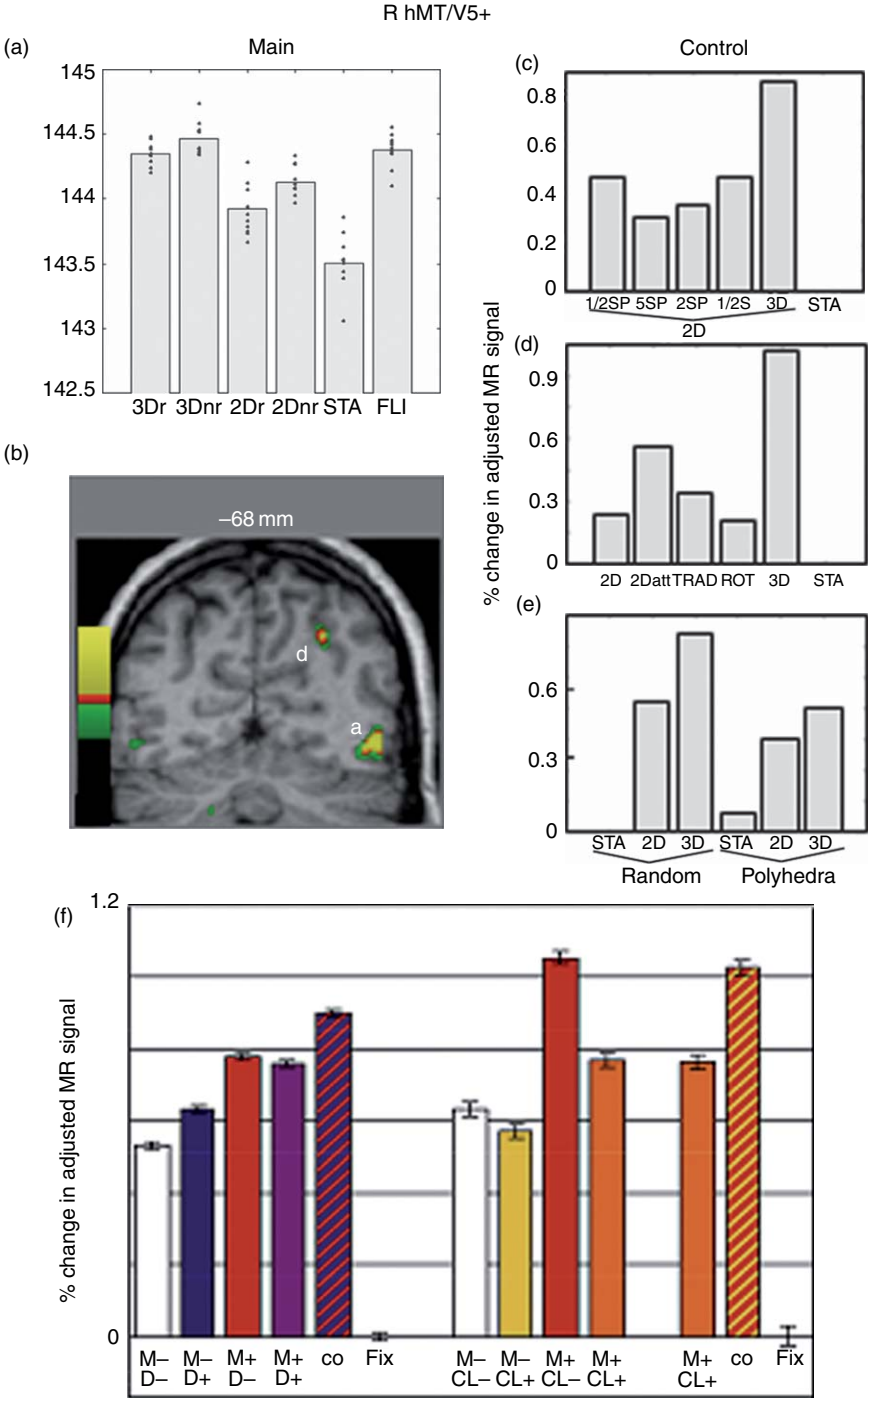
2.15.3.3 Monkey Functional Magnetic Resonance Imaging Studies

2.15.3.3.1 MT/V5 and satellites

The three fMRI studies using monkeys that have investigated the monkey cortical regions engaged in 3D SFM (Sereno, M. E. *et al.*, 2002; Vanduffel, W. *et al.*, 2002; Nelissen, K. *et al.*, 2006), all three report a strong activation of MT/V5 and the fundus of the superior temporal (FST) by 3D shape from motion stimuli compared to various controls. In particular, the MT/V5 3D SFM activation (Figure 12) has been obtained in a large number of animals (>10 monkeys), for a wide range of stimulus conditions (different types of random lines, random-dots surfaces) and in different animal states (anesthetized and awake monkeys, various levels of attention to the fixation target). This MT/V5 activation is therefore a robust link between the single-cell studies (Xiao, D. K. *et al.*, 1997a; Nguyenkim, J. D. and

DeAngelis, G. C., 2004) and the human activation of the MT/V5 complex (Orban, G. A. *et al.*, 1999; Vanduffel, W. *et al.*, 2002; Kriegeskorte, N. *et al.*, 2003), even if the exact same stimuli have yet to be tested in the two types of experiments.

In general, the hMT/V5 complex is described as including the homologs of the MST subparts, but in the case of 3D SFM it is important to stress the inclusion of the FST homolog in the complex. It is unclear why so little MSTd activation by 3D



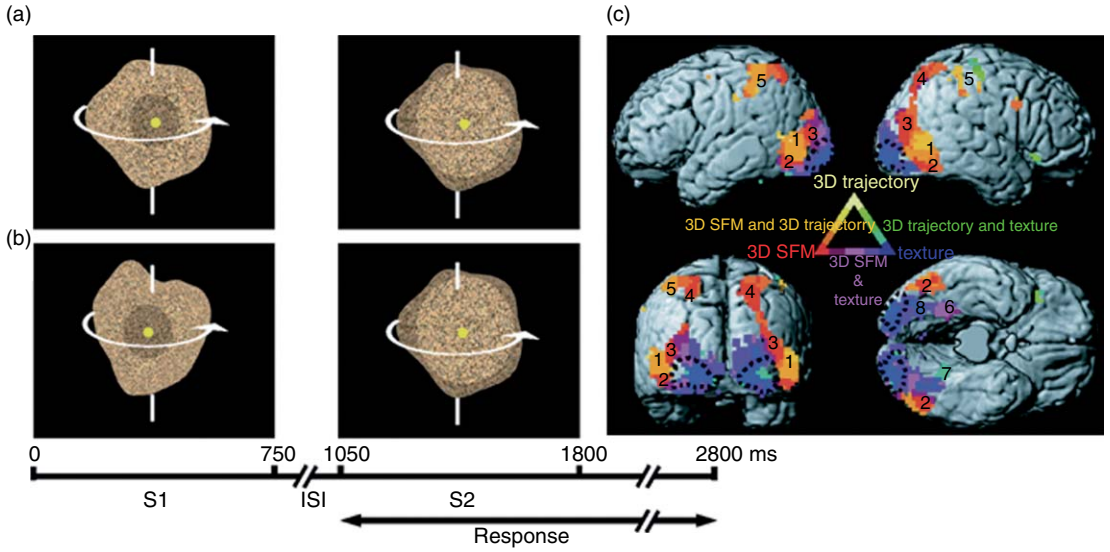


Figure 8 Distinguishing between 3D shape from motion and 3D motion pattern: (a–b) schematic representation of two texture trials: same trial (a) and different trial (b). Stimulus 1 and 2 show the central and peripheral dimming, respectively. The timing of the stimulus presentations and response period are indicated. The vertical line indicates the axis of rotation, slanted in the Z direction (outside the plane of the figure). Notice that the stimuli were identical in all five conditions (3 discrimination and 2 dimming detection conditions), only the aspect to which the subjects were instructed to pay attention was manipulated. (c) Activation patterns rendered on a standard brain (random effects, $P < 0.001$ uncorrected) Color scale indicates relative activation in the three different conditions: attention to 3D shape from motion (red), to axis of rotation (3D motion pattern, pale yellow), or to texture (blue). Dotted line indicates regions in which spatial attention had an effect. Numbers denote local maxima in regions significant at $P < 0.05$ (corrected for multiple comparisons): 1: hMT/V5+, 2: inferior temporal gyrus (ITG), 3: lateral occipital sulcus (LOS), 4: posterior intraparietal sulcus (IPS), 5: anterior IPS, 6: right collateral sulcus, 7: left middle lingual gyrus, 8: right posterior collateral sulcus with kind permission from Peuskens, H., Claeys, K. G., Todd, J. T., Norman, J. F., Van Hecke, P., and Orban, G. A. 2004. Attention to 3-D shape, 3-D motion and texture in 3-D structure from motion displays. J. Cogn. Neurosci. 16, 665–682.

SFM stimuli has been observed so far in the monkey fMRI studies. One possibility is the need to superimpose the speed gradients onto flow components.

2.15.3.3.2 Other cortical regions

Both in awake (Vanduffel, W. *et al.*, 2002) and anesthetized monkeys (Sereno, M. E. *et al.*, 2002) V2 and V3 are activated by 3D SFM stimuli. Whether or

Figure 7 Differential activation of right hMT/V5+ by 3D rotation displays compared to 2D translation displays: A–E data from Orban, G. A. *et al.* (1999); F data from Peuskens, H. *et al.* (personal communication); (a) activity profile of right hMT/V5+ from the main experiment. Adjusted magnetic resonance (MR) signal (resulting from proportional scaling), averaged over 11 subjects, is plotted for the six conditions of the main experiment: 3D rigid (3Dr), 3D nonrigid (3Dnr), 2D rigid (2Dr), 2D nonrigid (2Dnr), static (STA), and flickering (FLI) displays. The dots indicate individual responses. The profile is that of the most significant voxel at 52, −62, −4. Notice that in right hMT/V5+, the difference between 3Dr and 2Dnr is still significant ($z = 3.01$). (b) Single subject SPM showing the difference between viewing of 3Dr and 3Dnr displays and viewing of similar 2D displays in subject 3. Voxels reaching different levels of activation (yellow: $P < 0.05$, corrected; red: $P < 0.2$, corrected; green: $P < 0.001$, uncorrected) are shown on a coronal section at −68. Maximum Z score was 7.19 in this subject. The letters indicate the regions reaching statistical significance ($P < 0.05$, corrected for multiple comparisons): right hMT/V5+ (a), right ventral intraparietal sulcus (VIPS) (d). (c–e) Activity profiles of right hMT/V5+, obtained in control experiment 1, rigid case (c); control experiment 2 (d); and control experiment 3 (e). The percent change in adjusted MR signal, relative to viewing static displays, averaged over two (c) or three (d and e) subjects, is plotted for the different conditions: 2Dr with half the standard speed (1/2SP), with standard speed (SSP), with double speed (2SP), and with half-size (1/2S); 3Dr and STA in (C); 2Dr, 2Dr with attention (2Datt), rotation in the fronto-parallel plane (ROT), trajectory-in-depth (TRAD), 3Dr, and STA in (d); and random lines, static in 2D and 3D motion and polyhedra, static in 2D and 3D motion in (e). (f) Activity profiles (plotting MR signal changes relative to fixation) in an experiment in which two cues were combined: motion (M) and disparity (D) in left profile and motion (M) and closure (Cl) in right profile: Co: conflict between the two cues, + and − cue present, absent respectively; M–corresponds to translating lines and M+ to rotating lines. With kind permission from Orban, G. A., Sunaert, S., Todd, J. T., Van Hecke, P., and Marchal, G. 1999. Human cortical regions involved in extracting depth from motion. Neuron 24, 929–940.

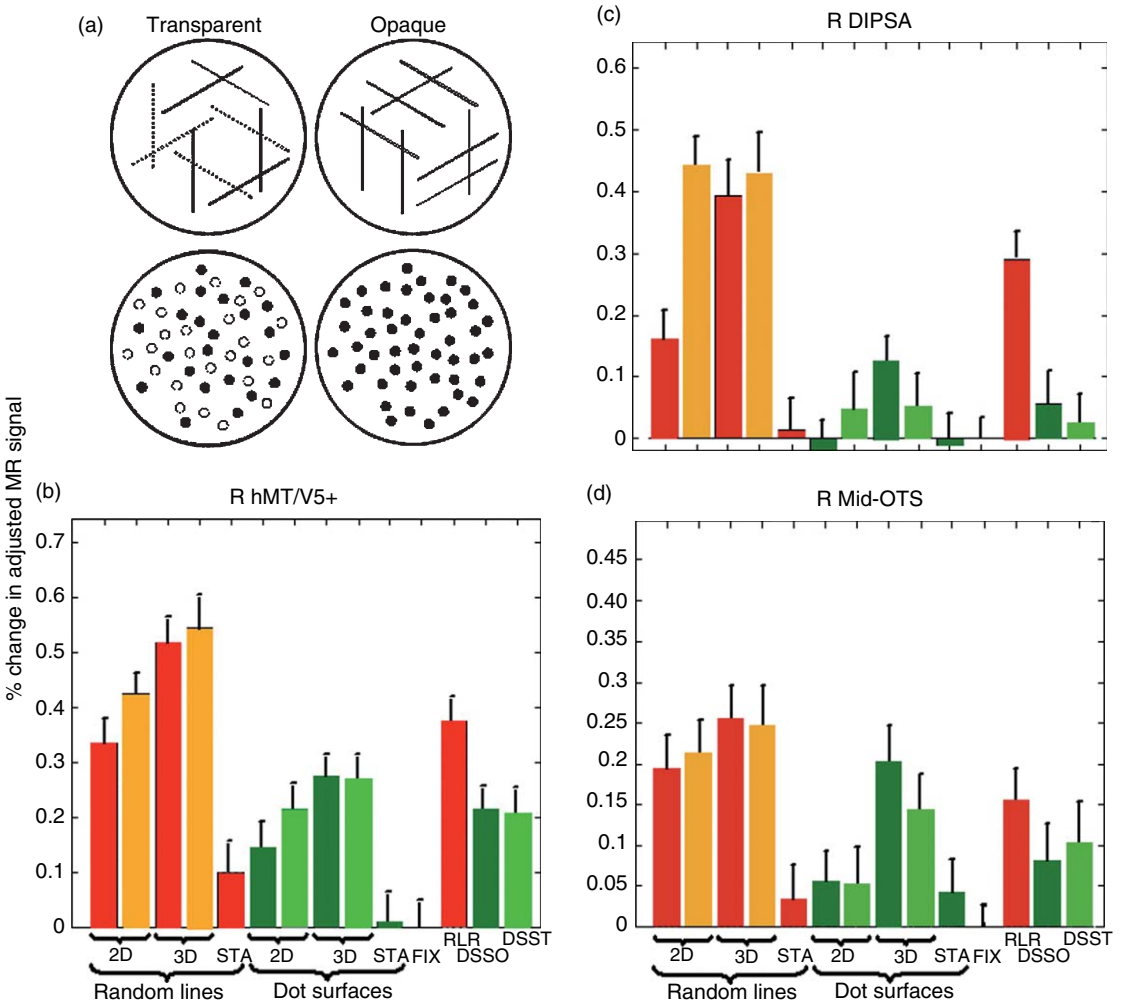

Figure 9 3D SFM: interaction with transparency in displays. (a) line and dot displays that undergo 3D rotation or 2D translation. The nine random (position and orientation) lines and 720 random (position) dots (lifetime 30 frames) moved at 3° s^{-1} in a circular aperture (9.9 diameter) in the center of the display. Lines (average projected length 4.5°) were constrained to lie on the faces of a randomly oriented cube centered in the aperture. Dots were constrained to lie on the surface of a sphere of the same diameter as the aperture. Lines and dots either rotated in depth around a vertical axis or translated in the plane. Open circles and stippled lines indicated lines and dots located on the back of the 3D object and moved in the opposite direction with respect to those on the front of the object. (b–d) Activity profiles of h MT/V5+ (b), DIPSA (c), and mid-OTS (d) in right hemisphere: the % magnetic resonance signal change (group of six subjects) compared to fixation is plotted for the 14 conditions analyzed. Red/orange bars indicate line surfaces, green bars are dot surfaces; opaque conditions are in red and dark green, transparent conditions in orange and light green. STA, stationary; FIX, fixation; RLR, random lines rotating in the image plane; DSSO, dot surfaces scrambled (vertical positions of dot trajectories) opaque; and DSST dot surfaces scrambled (vertical positions of dot trajectories) transparent (appear as a cloud of dots randomly distributed in a volume). Vertical bars indicate standard error of mean. With kind permission from Orban, G. A., Claeys, K., Nelissen, K., Smans, R., Sunaert, S., Todd, J., Wardak, C., Durand, J. B., and Vanduffel, W. 2006a. not this activation, limited to the stimulus edges, reflects the location in depth of the whole stimulus (Bakin, J. S. *et al.*, 2000) is unclear.

There is less agreement about the involvement of other cortical regions: Sereno M. E. *et al.* (2002) described further temporal activation sites in the lower and upper bank of the superior temporal sulcus (STS), beyond FST, which were not observed in the Vanduffel W. *et al.* (2002) study, as well as an anterior middle temporal sulcus (AMTS) activation, which might correspond to the weak TE activation observed by Vanduffel W. *et al.* (2002). In humans, random-dot stimuli were relatively more effective than random-line stimuli in occipitotemporal regions, and this

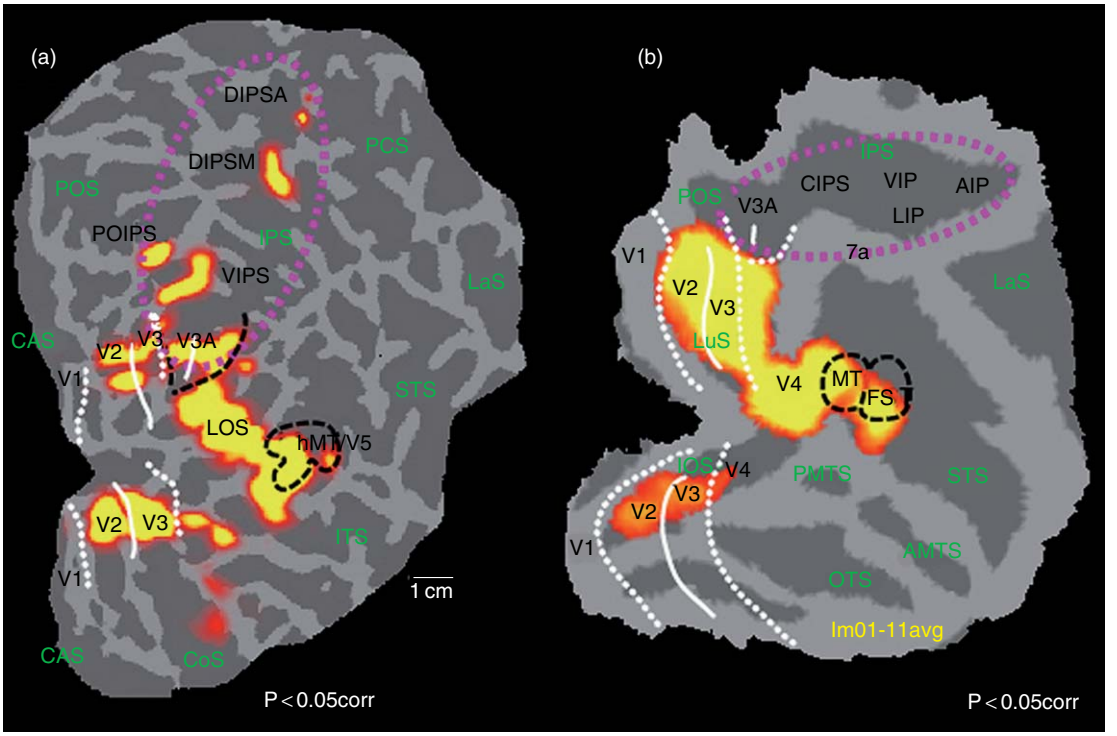

Figure 10 3D SFM network of human and monkey compared. SPMs for the subtraction viewing of 3D rotating lines minus viewing of 2D translating lines ($P < 0.05$, corrected for multiple comparisons) of a single human (a) and monkey (M4: b) subject projected on the posterior part of the flattened right hemisphere. White stippled and full lines: vertical and horizontal meridian projections (from separate retinotopic mapping experiments); black stippled lines: motion responsive regions from separate motion localizing tests; purple stippled lines region of interspecies difference encompassing V3 and intraparietal sulcus (IPS). AMTS, anterior middle temporal sulcus; CAS, calcarine sulcus; CoS, collateral sulcus; DIPSA, dorsal intrapatietal sulcus anterior; DIPSM, dorsal intraparietal sulcus medial; IOS, inferior occipital sulcus; ITS, inferior temporal sulcus; LaS, lateral sulcus; LOS, lateral occipital sulcus; LuS, lunate suclus; OTS, occipitotemporal sulcus; PCS, postcentral sulcus; PMTS, posterior middle temporal sulcus; POIPS, parieto-occipito intraparietal sulcus; POS, parieto-occipital sulcus; STS, superior temporal sulcus; VIPS, ventral intraparietal sulcus. Adapted from Vanduffel, W., Fize, D., Peuskens, H., Denys, K., Sunaert, S., Todd, J. T., and Orban, G. A. 2002. Extracting 3D from motion: differences in human and monkey intraparietal cortex. Science 298, 413–415. With kind permission from Orban, G. A., Fize, D., Peuskens, H., Denys, K., Nelissen, K., Sunaert, S., Todd, J., and Vanduffel, W. 2003. Similarities and differences in motion processing between the human and macaque brain: evidence from fMRI. Neuropsychologia 41, 1757–1768.

stimulus difference might explain the discrepancies between the two studies, as might the more stringent criterion used by Vanduffel W. *et al.* (2002) ($P < 0.05$ corrected for multiple comparisons).

Vanduffel W. *et al.* (2002) described an important species difference between monkey and human IPS, with the former being much less sensitive to 3D SFM than its human counterpart. Out of three monkeys tested in the original study, only one animal (M3) had a weak ($P < 0.001$ uncorrected for multiple comparisons) 3D SFM activation in what was described as VIP, but might also correspond to ventral LIP (Orban, G. A. *et al.*, 2006a). Subsequent testing of two more monkeys, both of whom had relatively weak stereopsis, disclosed a significant ($P < 0.05$ corrected for multiple comparisons) activation of the anterior lateral bank by 3D SFM in these two animals (Orban, G. A. *et al.*, 2006a). This activation might correspond to the activation described as LIP by Sereno M. E. *et al.* (2002). Yet these latter authors described several additional activation sites in and near the monkey IPS (multiple LIP sites, POJ, LOP) which were not observed in the Vanduffel W. *et al.* (2002) study. In this case stimulus differences are a less likely explanation, since random lines drive monkey parietal regions well (Vanduffel, W. *et al.*, 2002) and in human imaging random-line stimuli, as used by Vanduffel W. *et al.* (2002), engage the IPS 3D SFM regions more than random-dot stimuli do (Figure 9).

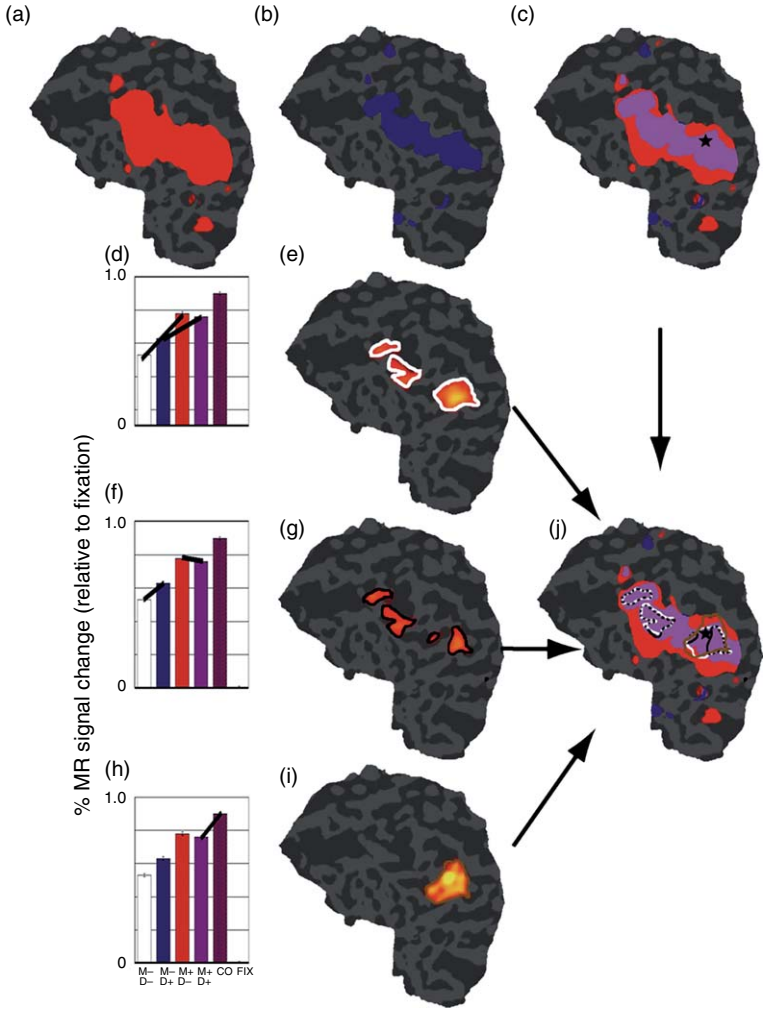

Figure 11 Combination of motion and stereo in the extraction of 3D shape (random-line stimuli, Peuskens, H., personal communication). SPMs (group, $n = 6$) plotting voxels significant ($P < 0.05$ corrected for multiple comparisons) in the single effect of 3D SFM (a), of 3D SFS (b), in the cue interaction in the motion regions (e), the cue interaction in the disparity regions (g) and in the subtraction cue conflict minus cue agreement (i) on the flattened hemisphere of the six subjects. The single effect SPMs are superimposed in c, and further combined with the outlines of interaction and conflict regions in (j). The activity profiles (plotting magnetic resonance signal changes relative to fixation) of right hMT/V5+ (asterisk) are plotted to illustrate the negative effect of stereo on the motion cue (d), the negative effect of motion on the stereo cue (f), and the conditions used to calculate the conflict effect (black lines in (h)).

2.15.4 The Extraction of Three-Dimensional Shape from Disparity or Stereo (Three-Dimensional SFS)

2.15.4.1 Single-Cell Studies

Neuronal selectivity for higher-order disparity has been documented mainly in two cortical regions: the caudal part of the lateral bank of IPS, caudal intraparietal (CIP), explored by Sakata and his collaborators and a small region in lower bank of the STS, TEs, explored by our group. Since much more information is available about TE neurons, the TE regions will be reviewed first and then CIP will then be compared to it (for reviews see Sakata, H. *et al.*, 2005; Orban, G. A. *et al.*, 2006b).

2.15.4.1.1 Higher-order disparity selectivity in TEs, part of the inferotemporal complex

The Janssen P. *et al.* (1999) study, reporting that a fraction of inferotemporal (IT) neurons were selective for 3D shape defined by disparity, was not only the first study to report selectivity for second-order

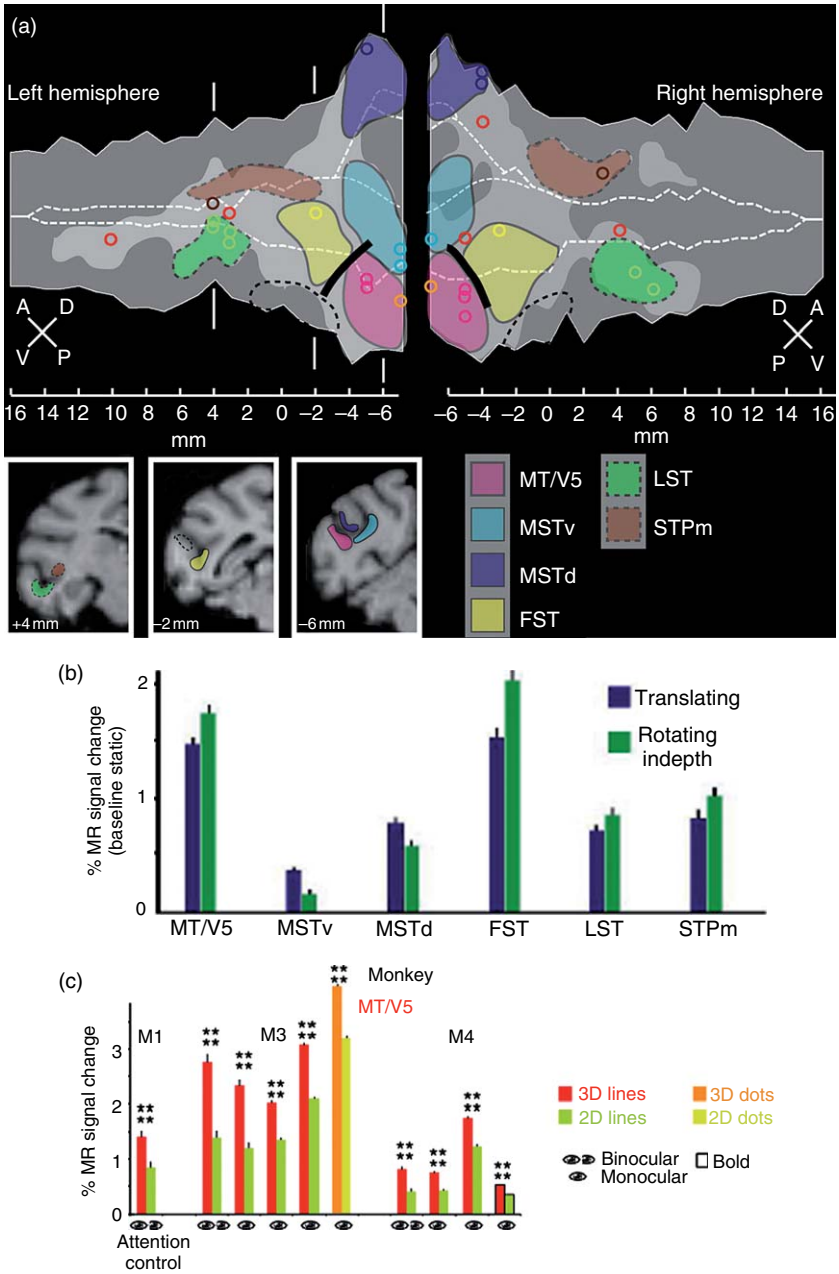

Figure 12 Monkey MT/V5 engaged by 3D SFM: (a) Overview of motion-responsive regions within the left and right STS. Boundaries of six motion-responsive regions are shown: MT/V5 (pink), MSTv (cyan), MSTd (blue), fundus of the superior temporal (FST) (yellow), STPm (brown), and LST (green). Boundaries that are less certain are indicated by dashed lines. The light gray overlay indicates the motion-responsive cortex identified with five motion contrasts. Colored circles correspond to SPM local maxima. The black solid line indicates the location of the VM representation that forms the border between areas MT/V5 and FST. The dashed black line indicates the region giving strong responses to static shapes, probably corresponding to (part of) TEO. At the bottom, three coronal sections (at -6, -2, and $+4$ mm, respectively, to the interaural plane) show the locations of the different regions: MT/V5, MSTv, and MSTd at level -6 mm; FST at -2 mm; and LST and STPm at $+4$ mm to the interaural plane. A, anterior; D, dorsal; P, posterior; V, ventral. (b) Magnetic resonance response profiles of the six STS motion regions: percentage of MR signal changes for random lines translating or rotating in depth compared with stationary control. Group data of three monkeys (M1, M3, and M5) are shown. (c) Activity profiles of area MT/V5. The different profiles for each animal are derived from a separate experiment. Each profile represents the average % signal change from the two hemispheres relative to the static control condition. Significance levels ($^{**} = P < 0.05$ corrected) are indicated for the right and left hemisphere (lower symbols) separately. ATT–: negative attention (high-acuity fixation task); black outline bold measurement rather than monocrystalline iron oxide nanoparticle (MION) measurement; vertical lines: standard error of means. With kind permission from Nelissen, K., Vanduffel, W., and Orban, G. A. 2006. Charting the lower superior temporal region, a new motion-sensitive region in monkey superior temporal sulcus. J. Neurosci. 26, 5929–5947 (a, b) and Vanduffel, W., Fize, D., Peuskens, H., Denys, K., Sunaert, S., Todd, J. T., and Orban, G. A. 2002. Extracting 3D from motion: differences in human and monkey intraparietal cortex. Science 298, 413–415 (c).

disparity stimuli, but it was also the first to report disparity selectivity as such in the ventral stream. Indeed, stereo was classically associated with the dorsal stream (Ungerleider, L. G. and Mishkin, M., 1982; Van Essen, D. C. *et al.*, 1992), although lesion studies had indicated some involvement of the ventral stream in stereoscopic processing (Cowey, A. and Gross, C. G., 1970; Ptito, A. *et al.*, 1991). Many subsequent studies have confirmed that stereo is processed in the ventral stream (Uka, T. *et al.*, 2000; Hinkle, D. A. and Connor, C. E., 2001; 2002; Watanabe, M. *et al.*, 2002; Tanabe, S. *et al.*, 2004; Hegdé, J. and Van Essen, D. C., 2005a; 2005b; Tanabe, S. *et al.*, 2005; Uka, T. *et al.*, 2005). The demonstration of higher-order selectivity was provided by showing that the selectivity for curved surfaces of opposite sign (convex and concave) did not depend on the position in depth of the surfaces. This position invariance criterion is reminiscent of the test used by Lagae L. *et al.* (1994) to demonstrate higher-order motion selectivity of MST neurons.

Subsequent studies (Janssen, P. *et al.*, 2000a) indicated that neurons selective for 3D shape defined by disparity (3D shape from disparity, 3D SFD) were not scattered throughout IT, but were concentrated in a small region in the rostral part of the lower bank of the STS. This region (Figure 13), labeled TEs, houses many 3D SFD selective neurons, in contrast to the convexity of IT. The two parts of IT also differ in their degree of binocular summation, which is stronger in TEs than in lateral TE (Janssen, P. *et al.*, 2000a). Since the anatomical connectivity of this lower STS region is also different from the remainder of the convexity (Saleem, K. S. *et al.*, 2000; Luppino, G., 2005), we (Janssen, P. *et al.*, 2000a) proposed that TEs is a separate cortical region linked to the IPS.

Finally, TEs neurons were shown to be endowed with another higher-order property which had been frequently postulated but never observed: the rejection of false matches such as those in anticorrelated stereograms (Janssen, P. *et al.*, 2003). In contrast to V1 neurons (Cumming, B. G. and Parker, A. J., 1997), TEs neurons, which are selective for 3D shape depicted by correlated RDS, do not respond selectively to anticorrelated RDS. In this respect anticorrelated RDS are similar to decorrelated RDS which also evoke no differential response from TEs neurons (Figure 14). Thus at the level of TEs what has been referred to as the stereo correspondence problem (Marr, D. and Poggio, T., 1979) is solved. This need not imply that it has not already been solved at some earlier level. Recent results suggest that the false matches are greatly reduced in V4 (Tanabe, S. *et al.*, 2004), but not in V2 (Allouni, A. K. *et al.*, 2005).

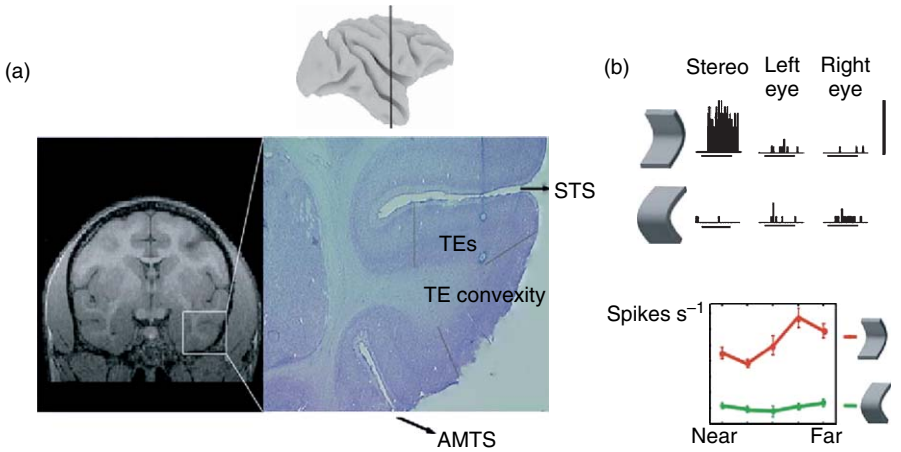

Figure 13 Defining characteristics and localization of higher-order disparity selective neurons in inferotemporal cortex. (a) Localization of recording on a magnetic resonance (MR) image (coronal section at level indicated) and histological section (monkey H); (b) Peristimulus time histograms (PSTHs) indicating responses to stereo and monocular stimuli and curves plotting average net responses to curved surfaces as a function of position in depth (1° range). Horizontal line indicates stimulus duration (300 ms) and vertical bar 90 spikes s^{-1}. Adapted from Janssen, P., Vogels, R., and Orban, G. A. 2000a. Selectivity for 3D shape that reveals distinct areas within macaque inferior temporal cortex. Science 288, 2054–2056. AMTS, anterior middle temporal sulcus; STS, superior temporal sulcus. The approximative locations of TFs and the convexity of TE are indicated. With kind permission from Orban, G. A., Janssen, P., and Vogels, R. 2006b. Extracting 3D structure from disparity. Trends Neurosci. 29, 466–473.

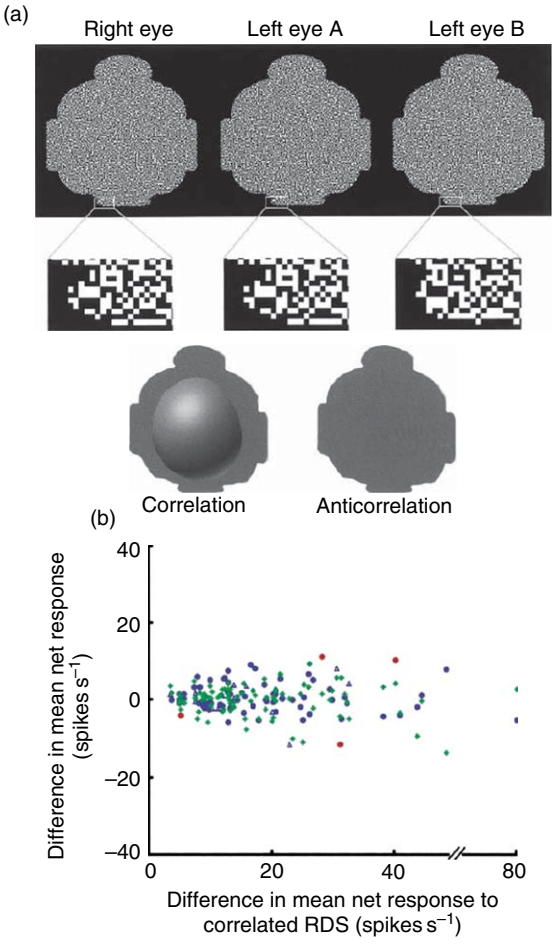

Figure 14 Rejection of false matches by TEs neurons. (a) Stimuli. The top row shows the monocular images for a correlated (right eye and left eye A) and an anticorrelated (right eye and left eye B) RDS in the correlation/anticorrelation test. The second row illustrates for zero disparity the inverted contrast polarity in the anticorrelated RDS (left and right panel) compared to the correlated RDS (left and middle panel). The bottom row shows a schematic illustration of the perceived 3D structure. (b) Population Analysis. Scatterplot of difference in mean net response to the anticorrelated (blue, circles: higher-order neurons; triangles: zero-order neurons) and decorrelated (green) RDSs plotted as a function of the difference in mean net response to the correlated RDS. Red circles: four neurons with significant response modulation to the anticorrelated RDS. With kind permission from Janssen, P., Vogels, R., Liu, Y., and Orban, G. A. 2003. At least at the level of inferior temporal cortex, the stereo correspondence problem is solved. Neuron 37, 693–701.

2.15.4.1.2 Exquisite coding of three-dimensional shape from disparity by TEs neurons

In the initial studies we emphasized the selectivity of TEs neurons for second-order disparity stimuli (Janssen, P. *et al.*, 1999; 2000a). In fact, TEs houses neurons selective for all three orders of depth signaled by disparity. Figure 15 shows an example of zero-order, first-order, and second-order disparity-selective neurons. The defining criterion for a higher-order neuron was a selectivity which did not reverse at any position in depth. This criterion supposes that vergence eye movements of the monkey are controlled. Generally we only recorded the position of only one eye, but we have shown that this suffices to detect vergence eye movements, provided enough trials are averaged (Janssen, P. *et al.*, 2000b). Furthermore, a number of higher-order neurons were recorded while we monitored positions of both eyes (Janssen, P. *et al.*, 2001). Thus, we were able to demonstrate the validity of our definition of higher-order neurons. In the initial study, this criterion was implemented by the requirement that the response to the preferred shape at its optimal position exceeds the response to the nonpreferred shape at any position (Janssen, P. *et al.*, 1999). Subsequently, this requirement was quantified by an index comparing the best position for the nonpreferred shape to the worst position of the preferred shape (Janssen, P. *et al.*, 2000b). The ratio of these responses did not exceed a factor of 2 in higher-order neurons and was generally smaller than 1.5. For the cell in Figure 15A the ratio exceeded 5. A simple disparity test with fronto-parallel surfaces sufficed to confirm that this cell was zero order: the cell was a near neuron (Poggio, G. F. and Fischer, B., 1977). First-order neurons were position-in-depth invariant and responded as well to the 3D shapes as to a planar 3D surface tilted in depth (Figure 15(b)). In the Liu Y. *et al.* (2004) study, these neurons were shown to be tuned for the tilt (3D orientation) in depth. Finally, second-order neurons were invariant for position in depth and responded selectively to shapes curved in depth but not to first-order stimuli (Figure 15(c)). In about half of them, the first-order approximation, a wedge, evoked a significantly weaker response than the original curved stimulus (Figure 15(c)). In the other half, this approximation was as effective as that stimulus. Note that zero-order approximations were effective in only a few higher-order neurons, as in Figure 15(b).

It is worthwhile emphasizing the exquisite sensitivity of TEs neurons for small changes in 3D structure. The difference between curved stimuli and their linear approximations is only one example. Most neurons remained selective for the sign of curvature up to the smallest amplitude of depth variation (0.03°) tested. In addition, most neurons

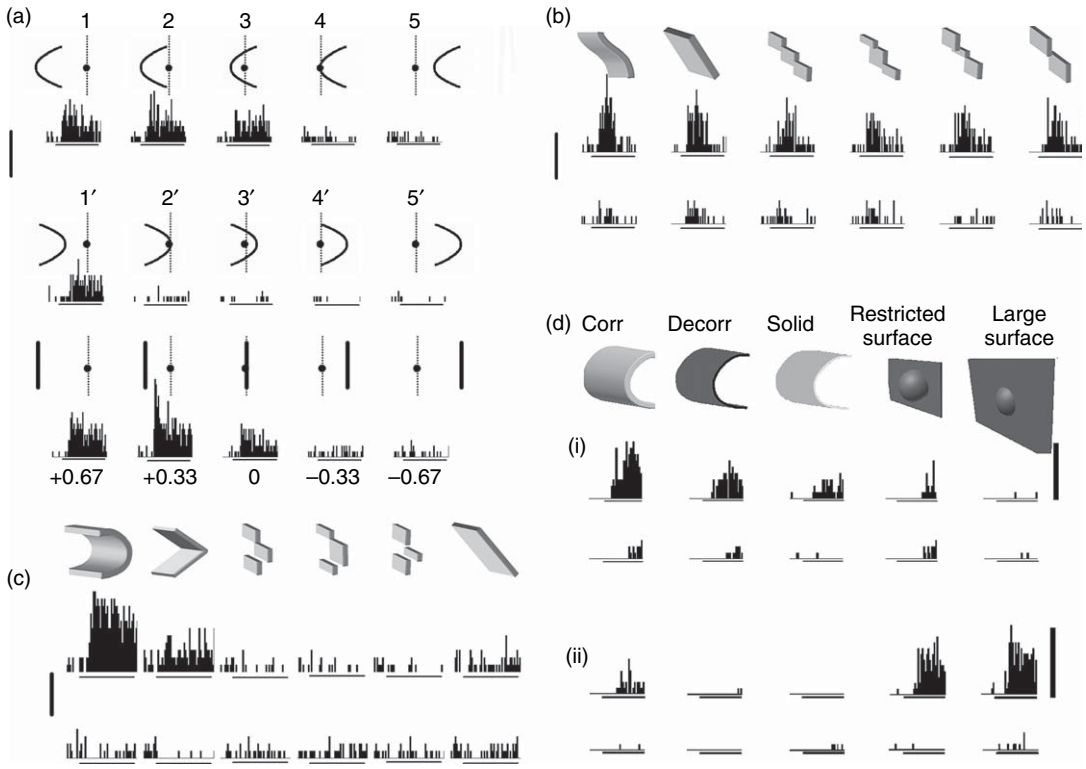

Figure 15 Types of TEs neurons. (a–c) Peristimulus time histograms (PSTHs) indicating average responses of zero-order (a), first-order (b), and second-order (c) selective neurons. (d) Responses of TEs neurons selective for the 3D shape of the edges of surfaces (i) and of texture inside the edges (ii). The horizontal lines below the PSTH indicate stimulus duration. In A all stimuli are indicated above the corresponding PSTHs, in B–D only the preferred stimulus polarity is shown. Vertical bars indicate 60 spikes s^{-1} (a), 30 spikes s^{-1} (b, c), and 65 spikes s^{-1} (d). corr, correlated; decorr, decorrelated. With kind permission of Orban, G. A., Janssen, P., and Vogels, R. 2006b. Extracting 3D structure from disparity. Trends Neurosci. 29, 466–473.

were sensitive to differences in the amplitude of depth variation in convex or concave stimuli. Their response usually decreased monotonically with decreasing amplitude, but in some cases was tuned to a preferred amplitude.

Selectivity for curvature of 3D surfaces could reflect selectivity for the 3D shape of either the edges or the texture pattern inside the edges. In fact, TEs neurons can be selective for both components of the surface stimuli (Janssen, P. *et al.*, 2001). The neuron in the top part of Figure 15D retains its selectivity with decorrelated RDS and solid stereograms in which only the boundary carries depth information, while losing it when the edges are removed in the doubly curved stimuli. This neuron was thus selective for the 3D shape of the edges. The neuron in the bottom part of Figure 15(d) reacted in exactly the opposite way and was selective for the 3D shape of the texture inside the edges. In the same study, we also showed that TEs neurons can encode the orientation of the 3D curvature and can, in all likelihood, combine selectivity for orthogonally oriented curvatures as captured by the shape index (Figure 2) of Koenderink J. J. (1990).

2.15.4.1.3 The invariance of three-dimensional shape selectivity in TEs

The 3D shape selectivity was found to be invariant for changes in fronto-parallel position and in size (Janssen, P. *et al.*, 2000b), as has been observed for 2D shape selectivity (Schwartz, E. L. *et al.*, 1983; Ito, M. *et al.*, 1995; Logothetis, N. K. and Sheinberg, D. L., 1996; Tanaka, K., 1996; Vogels, R. and Orban, G. A., 1996; Vogels, R., 1999). The invariance for fronto-parallel position complements the invariance for position in depth already reported in the first study (Janssen, P. *et al.*, 1999), defining a region in 3D space in which TEs neurons maintain their 3D shape selectivity.

The 2D shape selectivity of IT neurons has been shown to be cue invariant (Sáry, Gy. *et al.*, 1993; Tanaka, K. *et al.*, 2001). In the same way, the 3D

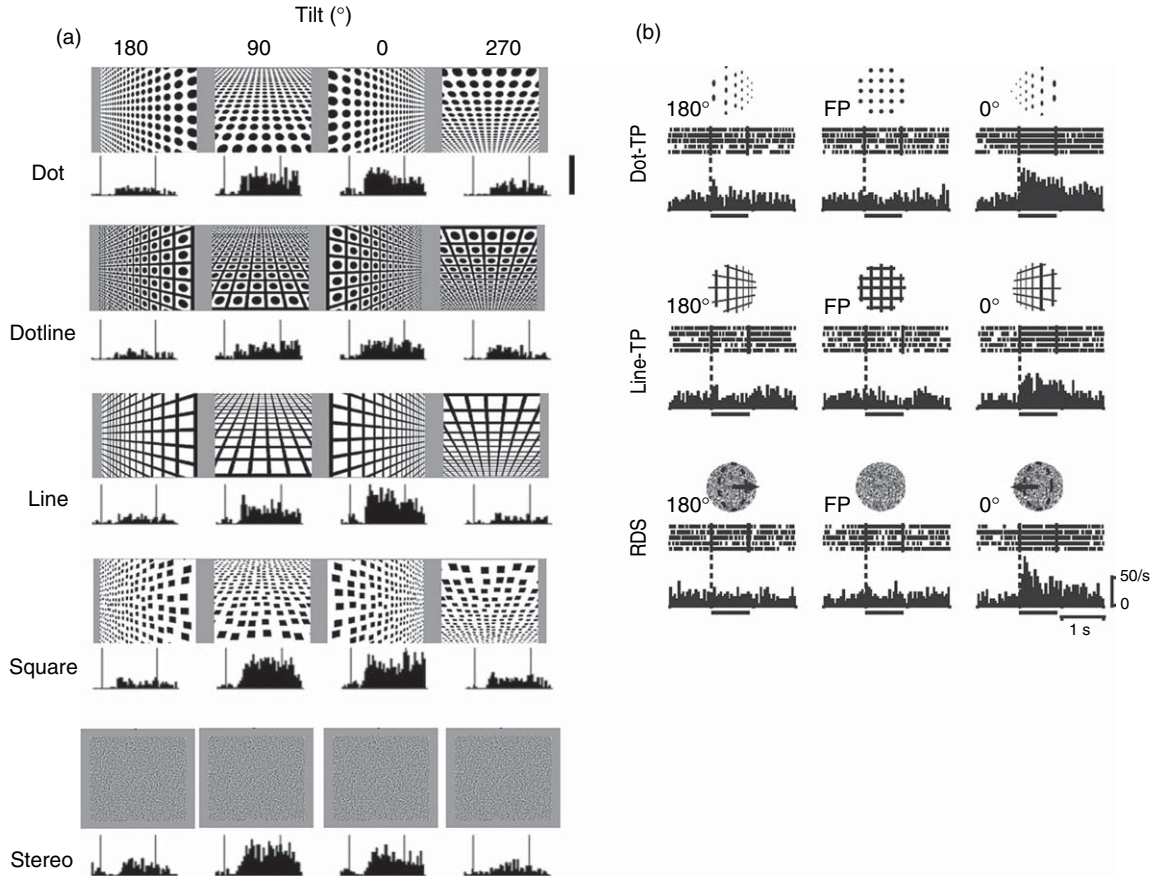

Figure 16 Average responses of TEs (a) and CIP (b) neurons to planar surfaces tilted in depth defined by disparity or different types of texture. Data from Liu Y. *et al.* (2004) and of Tsutsui K. *et al.* (2002). Stimulus duration is indicated by vertical lines in a and horizontal line in b; vertical bar in A indicates 87 spikes s^{-1}. Textures in A not drawn to size (about 7° in diameter and enclosed in a 2D shape, to match well-known shape selectivity of IT neurons). With kind permission from Orban, G. A., Janssen, P., and Vogels, R. 2006b. Extracting 3D structure from disparity. Trends Neurosci. 29, 466–473.

shape selectivity of TEs neurons has also been shown to be depth-cue invariant. We opted for a comparison of selectivity for the disparity and texture cues (see below). TEs neurons are selective for tilt specified by disparity but also those specified by texture gradients (Liu, Y. *et al.*, 2004), and preferred tilt is similar for the two cues (Figure 16A). In addition, the selectivity for tilt specified by texture was shown to be invariant for texture type, for slant and for binocular versus monocular presentations.

2.15.4.1.4 Selectivity of caudal intraparietal neurons for first-order disparity

Shikata E. *et al.* (1996) reported that neurons in the caudal part of the lateral bank of IPS were selective for the tilt of stereoscopic surfaces. This caudal region has been referred to as cIPS (Sakata, H. *et al.*, 1997), CIP (Taira, M. *et al.*, 2000), or posterior LIP (Nakamura, H. *et al.*, 2001) and probably corresponds to pIPS as defined by Denys K. *et al.* (2004) and to LOP as defined by Lewis J. W. and Van Essen D. C. (2000). Although that initial study established the disparity selectivity of the CIP neurons, it is only in Taira M. *et al.* (2000) that the higher-order nature of the selectivity was established by showing invariance for changes in the fixation distance. It has been reported in abstract form that CIP neurons have also solved the correspondence problem (Katsuyama, N. *et al.*, 2004). Importantly, Tsutsui K. *et al.* (2001) have demonstrated that inactivation of CIP interferes with judgments about surface tilt.

So far, only first-order selectivity has been demonstrated in CIP, although second-order selectivity has also been suggested to be present

(Katsuyama, N. *et al.*, 2005). Cue convergence has been documented for CIP neurons, for the combination of texture and disparity (Tsutsui, K. *et al.*, 2002, Figure 16(b)), as well as for perspective and disparity (Tsutsui, K. *et al.*, 2001).

Finally, CIP neurons, rather than being selective for the orientation in depth of surfaces (surface orientation selective), can be selective for the orientation in 3D of elongated stimuli (axis orientation selective, Sakata, H. *et al.*, 1998).

2.15.4.1.5 Three-dimensional shape from disparity selectivity in other cortical regions

V1 neurons display no higher-order disparity selectivity (Nienborg, H. *et al.*, 2004) and are selective for anticorrelated RDS as well as for correlated RDS (Cumming, B. G. and Parker, A. J., 1997). Thus, most properties of TEs and CIP neurons reflect processing beyond V1. V4 provides input to IT, and V4 neurons are selective for the orientation in depth of elongated stimuli (Hinkle, D. A. and Connor, C. E., 2002) but not for surfaces curved in depth (Hegdé, J. and Van Essen, D. C., 2005). Thus, either TEs neurons acquire their higher-order selectivity through local connections in TEs or TEO, or TEs receives its selective input from IPS. Indeed it has been suggested that selectivity for 3D orientation is a property of neurons along the lateral bank of IPS (Nakamura, H. *et al.*, 2001). The selectivity of anterior intraparietal (AIP) neurons for real objects supposedly supports their role in the control of grasping (Murata, A. *et al.*, 2000). Whether or not this selectivity is based on a selectivity for 3D shape is presently investigated (Durand, J. B. *et al.*, 2006).

Some 3D orientation selectivity, based on disparity has been reported for MT/V5 neurons (see above), which also have intermediate properties with respect to responses to aRDS (Nguyenkim, J. D. and DeAngelis, G. C., 2003; Krug, K. *et al.*, 2004). Nguyenkim J. D. and DeAngelis G. C. (2003) reported that the preferred tilt of MT/V5 neurons, specified by disparity did not depend on slant. Thus the origin of higher-order disparity selectivity and the extent of this selectivity throughout the visual system remain unclear. The stronger selectivity in CIP and TEs compared to MT/V5, however, suggests that MT/V5 represents one of the early stages of 3D shape and 3D surface orientation extraction.

2.15.4.2 Imaging Studies

Very few studies so far have been specifically devoted to the extraction of 3D shape from stereo, although several studies in human and monkeys are currently ongoing in our group (Janssen, P. *et al.*, 2002; Durand, J. B. *et al.*, 2006a; 2006b). Tsao D. Y. *et al.* (2003) used a large checkerboard stimulus with random disparity levels in the different checks as a first-pass stimulus for 3D structure. In both species these authors observed an activation in V3A and the abutting posterior part of the IPS. In monkeys this activation included CIP. Welchman A. E. *et al.* (2005) tested for selectivity for slant defined by disparity in early retinotopic regions as well as hMT/V5+ and LOC. These authors failed to observe a significant rebound from adaptation for changes in slant defined by disparity in any of the regions studied. Preliminary data (Figure 11) suggest that similar human cortical regions are engaged by 3D SFS and 3D SFM.

2.15.5 Extraction of Three-Dimensional Shape from Static Monocular Cues

2.15.5.1 Single-Cell Studies

The difficulty in demonstrating a selectivity of single IT neurons for first- or second-order gradients of texture concerns the need to provide a control for simple texture or pattern selectivity of these neurons (Tanaka, K. *et al.*, 1991). Hence we adopted the strategy to study the invariance of TEs neurons for first- and second-order gradients specified by both disparity and texture. The initial study was done with single curved surfaces (Liu, Y. *et al.*, 2002) for which TEs neurons show limited selectivity in the texture case. We subsequently switched to linear texture gradients to which TEs neurons are much more sensitive and were able to show cue invariant processing by TEs of disparity and texture gradients (Liu, Y. *et al.*, 2004, see above). These authors showed that the preferred tilt specified by texture did not depend on slant, suggesting that slant and tilt are separable, in agreement with psychophysical results (Norman, J. F. *et al.*, 2006). For CIP neurons, Tsutsui K. *et al.* (2002) likewise demonstrated selectivity for tilt to texture gradients combined with selectivity of disparity gradients.

For shading little is know about neuronal processing, although Hanazawa A. and Komatsu H. (2001)

demonstrated that a number of V4 neurons are selective for the direction of illumination, a critical step for the extraction of 3D shape from shading (Khang, B. G. *et al.*, 2003; Koenderink, J. J. *et al.*, 2004).

2.15.5.2 Imaging Studies: Need for Two-Dimensional Shape Controls

Three studies (Humphrey, G. K. *et al.*, 1997; Taira, M. *et al.*, 2001; Kourtzi, Z. *et al.*, 2003) have been devoted the extraction of 3D shape from shading with conflicting results, some emphasizing early retinotopic regions, others LOC or IPS regions. All three studies suffer from the lack of controls for 2D shape sensitivity as all 3D-shape stimuli also contain clear 2D-shape elements and adaptation effects or discrimination might be based on these spurious 2D cues rather than the 3D percept.
